Across the small number of studies that examined potential copollutant confounding of the relationship between long-term $PM_{2.5}$ exposure and lung cancer mortality and incidence, there is little evidence of copollutant confounding by O_3 with more limited information available to assess potential copollutant confounding for the other gaseous pollutants and particle size fractions. However, to date, studies have not systematically evaluated copollutant confounding across the gaseous pollutants.

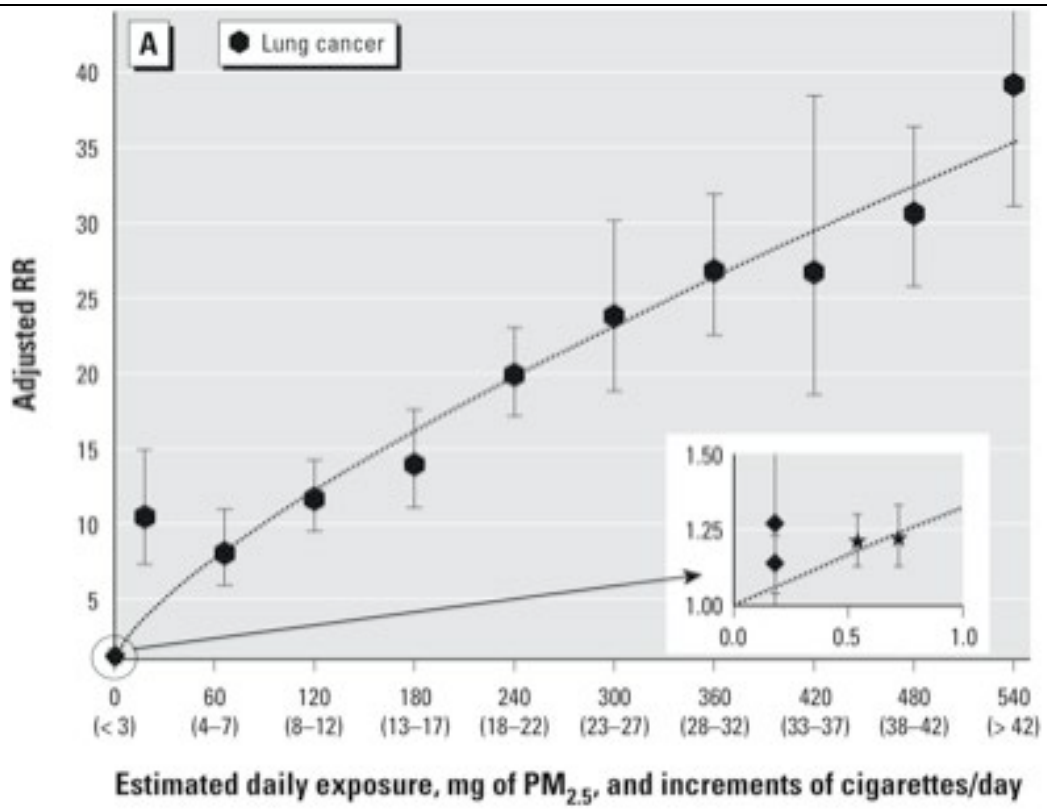
10.2.5.1.4 Concentration-Response (C-R) Relationship

Epidemiologic studies that examined the C-R relationship between long-term $PM_{2.5}$ exposure and mortality have generally found evidence of a linear, no threshold relationship (Section 11.2.4). However, fewer studies have examined the C-R relationship for cause-specific mortality outcomes, including lung cancer. Recent cohort studies of both lung cancer mortality and incidence have examined both the shape of the C-R relationship along with whether there is evidence of a threshold, or level below which there is no effect.

Across the studies evaluated, a few provided information on the shape of the $PM_{2.5}$-lung cancer mortality (Lepeule et al., 2012) and lung cancer incidence (Puett et al., 2014; Raaschou-Nielsen et al., 2013) C-R relationship, but did not extensively discuss the results. Lepeule et al. (2012) in the HSC cohort along with Puett et al. (2014) in the NHS cohort and Raaschou-Nielsen et al. (2013) in the ESCAPE study reported no evidence for deviations from linearity in the shape of the C-R relationship when examining alternative models. Additionally, Cesaroni et al. (2013) in the RoLS cohort examined a 20% random sample of the full cohort to assess the C-R relationship, but the small sample size resulted in an underestimation of the $PM_{2.5}$-lung cancer mortality association and an inability to fully characterize the C-R relationship. Although these studies provide limited information on the shape of the $PM_{2.5}$-lung cancer mortality and incidence C-R relationship, studies by Pope et al. (2011) using the ACS cohort and Tomczak et al. (2016) using the CNBSS cohort conducted more extensive analyses.

Pope et al. (2011) examined lung cancer mortality, but to convey the public health burden associated with exposures to $PM_{2.5}$ of ambient origin compared the shape of the C-R relationship for lung cancer mortality across three different exposures: active smoking, SHS, and ambient $PM_{2.5}$ exposures. For this analysis the authors focused on only 6 years of follow-up due to the lack of smoking information after initial enrollment. Pope et al. (2011) calculated adjusted relative risks (RRs) for lung cancer

mortality due to smoking status using the ACS cohort data, and relied upon RRs from other cohort studies of lung cancer mortality due to long-term $PM_{2.5}$ exposure and SHS. Using the adjusted RRs and estimates of: average inhaled dose of $PM_{2.5}$ from active smoking; average daily dose of inhaled $PM_{2.5}$ based on the range of $PM_{2.5}$ concentrations from recent U.S.-based cohort studies and average inhalation rates; and dose from SHS exposure based on approximate $PM_{2.5}$ exposures and average inhalation rates, Pope et al. (2011) fit an integrated-exposure response function using a simple power function. This functional form was selected because it allows for nonlinearity in the C-R relationship (Pope et al., 2011). In a plot of the relative risks for lung cancer mortality for ambient $PM_{2.5}$ exposure, SHS, and active smoking in relation to the estimated daily dose of $PM_{2.5}$ from different increments of cigarettes per day in smokers compared to never smokers, the authors observed evidence of a nearly linear relationship (Figure 10-5). This relationship persisted when examining lung cancer mortality in both men and women, and when accounting for smoking duration.

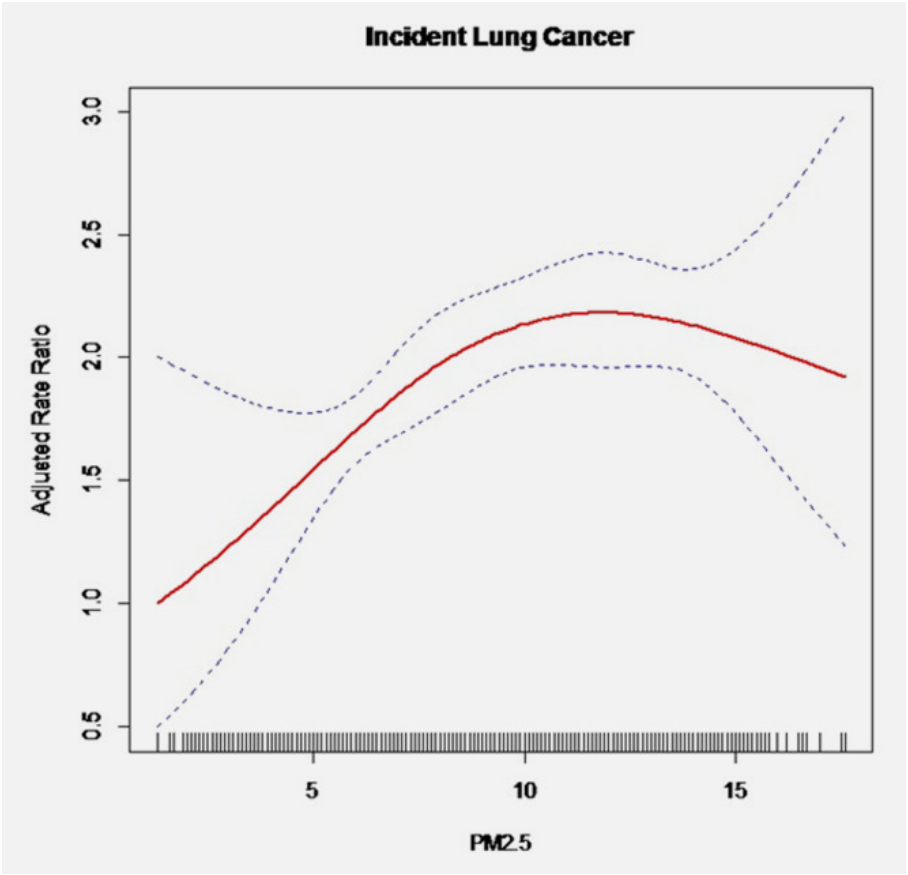


Note: Inset represents RR due to ambient $PM_{2.5}$ exposure and SHS. Diamonds = RR from studies of long-term $PM_{2.5}$ exposure and lung cancer mortality; stars = pooled RR estimates from studies of SHS and lung cancer mortality.

Source: Permission pending, Pope et al. (2011).

Figure 10-5 Adjusted relative risk (RR) for lung cancer mortality plotted over estimated daily dose of $PM_{2.5}$ (milligrams) and increments of cigarette smoking (cigarettes per day) compared to never smokers.

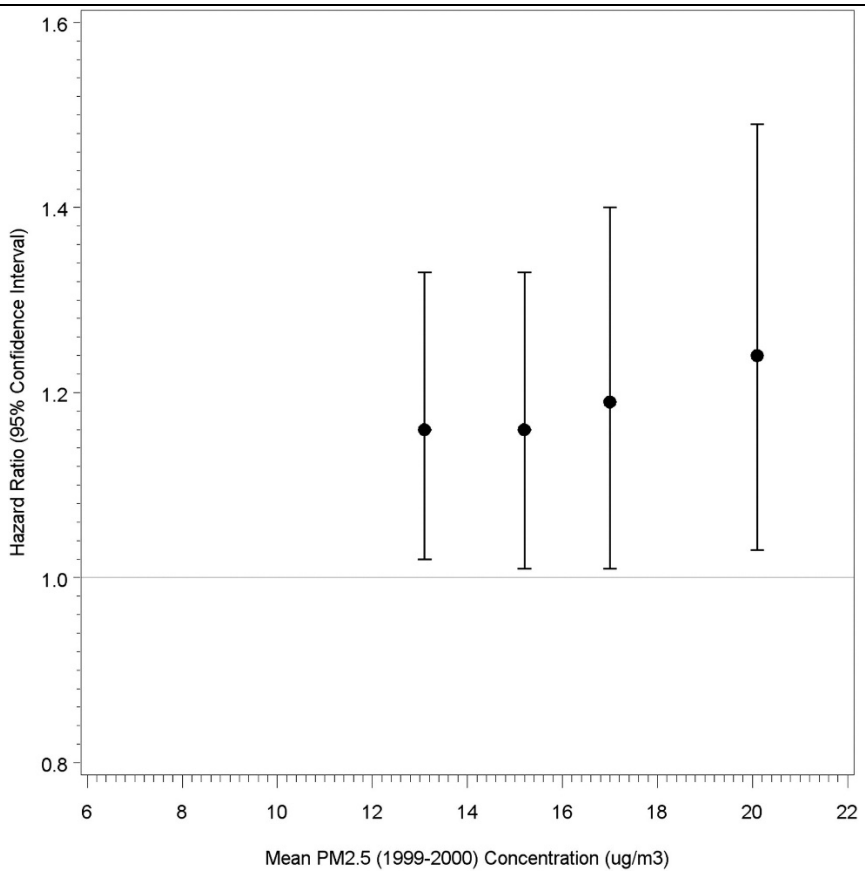
Tomczak et al. (2016) examined the shape of the C-R relationship for lung cancer incidence using the CNBSS. To examine whether there was evidence of nonlinearity in the C-R relationship, the authors considered a model with a natural cubic spline and 3 df. As depicted in Figure 10-6, Tomczak et al. (2016) observed evidence of nonlinearity in the $PM_{2.5}$-lung cancer incidence C-R relationship, which was depicted by a linear relationship up until approximately 12 µg/m^3 which then flattened out. The results of Tomczak et al. (2016) in this cohort of women differs from the examination of the C-R relationship in women by Pope et al. (2011) where the shape was found to be linear, which was consistent with the results of the full cohort. Although there is ambiguity in the shape of the C-R relationship above 12 µg/m^3 both Tomczak et al. (2016) and Pope et al. (2011) provide evidence of a linear C-R relationship in the range of $PM_{2.5}$ concentrations observed in the U.S.



Source: Permission pending, Tomczak et al. (2016).

Figure 10-6 Concentration-response (C-R) relationship between long-term $PM_{2.5}$ exposure and lung cancer incidence using a natural cubic spline and 3 degrees of freedom (df) in the Canadian National Breast Cancer Screening Survey (CNBCSS) cohort.

In addition to the studies that formally evaluated the C-R relationship, other studies used cut point analyses to examine whether there was evidence of a threshold or if the risk of lung cancer mortality or incidence varied across the range of $PM_{2.5}$ concentrations in each study. Turner et al. (2011) in the analysis of never smokers in the ACS-CPS II cohort examined the lung cancer mortality association across percentiles of the $PM_{2.5}$ distribution. When examining each percentile to the referent category, i.e., $PM_{2.5}$ concentrations less than 11.8 μg/m^3, the authors found relatively consistent associations with 95% confidence intervals increasing at higher concentrations, which is indicative of lower data density within those ranges of $PM_{2.5}$ concentrations (Figure 10-7).



Note: Cut-points represent the 25th (11.8 μg/m^3), 50th (14.3 μg/m^3), 75th (16 μg/m^3), and 90th (17.9 μg/m^3) percentiles.
Source: Permission pending, Turner et al. (2011).

Figure 10-7 Fully adjusted hazard ratios (95% confidence intervals) for lung cancer mortality in categorical analyses of mean $PM_{2.5}$ (1999−2000) concentrations in never smokers in the American Cancer Society-Cancer Prevention Study II (ACS-CPS II) cohort.

The results of Turner et al. (2011) in an analysis of lung cancer mortality, are consistent with those of Hystad et al. (2013) when examining lung cancer incidence in the NECSS cohort. In quintiles

that encompassed $PM_{2.5}$ concentrations less than those observed in Turner et al. (2011), ranging from less than 9.0 μg/m^3 for the referent category and above 14.7 μg/m^3 for the 5th quintile, the OR for long-term $PM_{2.5}$ exposure and lung cancer incidence ranged from 1.09−1.18, while the full cohort observed an OR = 1.14.

Instead of comparing $PM_{2.5}$-lung cancer incidence associations across a range of concentrations, Raaschou-Nielsen et al. (2013) in the ESCAPE study conducted a cut-point analysis to examine whether there was evidence of an association between long-term $PM_{2.5}$ exposure and lung cancer incidence below defined $PM_{2.5}$ concentrations. In the cut-point analysis, the authors excluded all participants with assigned $PM_{2.5}$ exposures that were above designated values (i.e., 10, 15, 20, and 25 μg/m^3). Across each of the cut-point values, Raaschou-Nielsen et al. (2013) reported consistent positive associations across each cut-point although confidence intervals were large due to the limited sample size for each cut-point value (HRs: 10 μg/m^3: 1.20 [95% CI: 0.55, 2.66]; 15 μg/m^3: 1.11 [95% CI: 0.85, 1.45]; 20 μg/m^3: 1.14 [95% CI: 0.90, 1.45]; 25 μg/m^3: 1.13 [95% CI: 0.90, 1.43]). The combination of results from cut-point analyses by Turner et al. (2011), Hystad et al. (2013), and Raaschou-Nielsen et al. (2013) collectively provide evidence indicating no threshold down to the lowest cut-point examined in each study (e.g., 9−11.8 μg/m^3).

Across the studies that examined long-term $PM_{2.5}$ exposure and lung cancer mortality and incidence, evidence from analysis of the shape of the C-R relationship, cut point analyses, and threshold analyses all support a no-threshold, linear relationship across the range of $PM_{2.5}$ concentrations observed in the U.S. Although Tomczak et al. (2016) observed a potentially nonlinear C-R relationship, this plateauing of the $PM_{2.5}$ association occurred at concentrations higher than those observed in many areas of the U.S., and was not consistent with the results of Pope et al. (2011) when focusing on women in the ACS-CPS II cohort.

10.2.5.1.5 Summary

Since the completion of the 2009 PM ISA there has been a dramatic increase in the number of studies that examined the relationship between long-term $PM_{2.5}$ exposure and lung cancer mortality and incidence using both previously examined cohorts as well as new cohorts. Collectively, these studies provide evidence of generally consistent, positive associations with both lung cancer mortality and incidence (Figure 10-3). These associations were observed across studies that adjusted for smoking status and exposure to SHS as well as those studies that had no direct measures of smoking status or used proxy measures to adjust for smoking.

In studies that conducted analyses on never smokers almost all of the studies, except a few conducted in Canada (Tomczak et al., 2016; Hystad et al., 2013) provided evidence of consistent positive associations. The positive associations for lung cancer in never smokers were confirmed by Turner et al. (2011) in a study of only never smokers in the ACS-CPS II cohort. The limited number of studies that

examined potential copollutant confounding reported that $PM_{2.5}$-lung cancer mortality and incidence associations remained relatively unchanged, specifically for O_3, with less evidence for other pollutants. Additionally, an examination of the C-R relationship and whether a threshold exists provided evidence that supports a no-threshold, linear relationship along the $PM_{2.5}$ concentrations observed in most locations within the U.S., specifically at concentrations representative of the lowest cut-point examined in studies, 9−11.8 μg/m^3, and where analyses of the C-R curve depict a widening of confidence intervals, ≈6 μg/m^3.

The collective body of evidence for lung cancer mortality and incidence detailed within this section, forms a substantial portion of the evidence included in recent meta-analyses of $PM_{2.5}$ and lung cancer risk, i.e., the meta-analyses did not delineate between lung cancer mortality and incidence in estimating the overall lung cancer risk (Chen et al., 2015; Yang et al., 2015; Cui et al., 2014; Hamra et al., 2014). Although the criteria for study inclusion varied across each of these meta-analyses they all reported evidence of a positive association between long-term $PM_{2.5}$ exposure and lung cancer risk (Figure 10-3). Specifically, the Hamra et al. (2014) meta-analysis, which formed a strong basis for the IARC conclusion on PM and lung cancer, included the majority of the studies evaluated within this section, the sole difference being this section did not focus on those studies that did not directly measure $PM_{2.5}$.

10.2.5.2 Other Cancers

The 2009 PM ISA concluded that there was no epidemiologic evidence supporting associations between long-term PM exposure in organs or systems other than the lung. However, the overall body of evidence was extremely limited. Since the completion of the 2009 PM ISA a number of studies have explored the relationship between long-term $PM_{2.5}$ exposure and other cancers including, but not limited to the breast and brain, with the majority focusing on cancer incidence. Of these studies, some had inherent limitations, such as an ecologic study design, and, therefore, are not the focus of this section and are available at: https://hero.epa.gov/hero/particulate-matter. Study characteristics including $PM_{2.5}$ concentrations, study population, and exposure assignment approach for the studies that examined other cancer sites are detailed in Table 10-6.

Table 10-6 Study specific details and $PM_{2.5}$ concentrations from recent that examined long-term $PM_{2.5}$ exposure and cancer in other organs or systems.

[f]Wong et al. (2016) examined a range of cancers including all malignant, all digestive organs, lung, breast, female genital, male genital, urinary, and lymphohematopoietic.

[g]Heck et al. (2013) examined a number of types of childhood cancers including leukemia.

[h]Only 2 (DCH, Denmark [1993−1997] and VHM and PP, Austria [1985−2005]) of the 4 escape cohorts examined measured $PM_{2.5}$.

[i]397 cases of acute lymphoblastic leukemia and 82 cases of acute myeloid leukemia.

†Studies published since the 2009 PM ISA.

10.2.5.2.1 Breast Cancer

Hart et al. (2016) and Reding et al. (2015) examined the association between long-term $PM_{2.5}$ exposure and breast cancer incidence in two U.S.-based cohorts, NHS II and Sister Study cohorts, respectively. In both studies, the authors observed relatively little evidence of an association overall for

breast cancer incidence or by hormone receptor subtype. Hart et al. (2016) using a 48-month average of $PM_{2.5}$ concentrations reported a HR = 0.95 (95% CI: 0.89, 1.01) for breast cancer incidence, which is similar to the results observed using a cumulative exposure metric (quantitative results not reported). Reding et al. (2015) also reported relatively little evidence for an association with breast cancer incidence using annual average $PM_{2.5}$ concentrations, HR = 1.04 (95% CI: 0.94, 1.16). The results of both U.S.-based studies are consistent with Andersen et al. (2016) in Denmark within the Danish Nurse Cohort (DNC) study, which provided no evidence of an association between 3-year running mean of $PM_{2.5}$ concentrations and breast cancer incidence (HR = 1.00 [95% CI: 0.87, 1.14]). However, in a study conducted at much higher $PM_{2.5}$ concentrations (>30 μg/m^3) in Hong Kong, Wong et al. (2016) reported a positive association with breast cancer mortality (HR = 1.34 [95% CI: 1.12, 1.60]).

10.2.5.2.2 Brain Cancer

The examination of long-term $PM_{2.5}$ exposure and brain cancer consisted of studies focusing on both incidence (Jørgensen et al., 2016) and mortality (McKean-Cowdin et al., 2009). In the DNC study, which consisted of female nurses over the age of 44, Jørgensen et al. (2016) used a 3-year running average of $PM_{2.5}$ concentrations and found evidence of a weak positive association for brain tumor incidence (HR = 1.09 [95% CI: 0.72, 1.65]), but no evidence of an association when focusing on malignant brain tumors (HR = 0.97 [95% CI: 0.47, 2.05]). The lack of an association with brain cancer incidence was supported by the results of McKean-Cowdin et al. (2009), using the ACS-CPS II cohort, when examining brain cancer mortality. When using three different exposure metrics representing $PM_{2.5}$ concentrations from 1979−1983 (RR = 0.94 [95% CI: 0.87, 1.01]), 1999−2000 (RR = 0.98 [95% CI: 0.89, 1.09]), and the average of the two time periods (RR = 0.95 [95% CI: 0.86, 1.05]), the authors reported no evidence of an association with brain cancer mortality.

10.2.5.2.3 Liver Cancer

Recent studies conducted in Taiwan (Pan et al., 2016) and Europe (Pedersen et al., 2017) have examined the relationship between long-term $PM_{2.5}$ exposure and liver cancer incidence. Pan et al. (2016) within the Risk Evaluation of Viral Load Elevation and Associated Liver Disease/Cancer-Hepatitis B Virus (REVEAL-HBV) cohort in Taiwan examined long-term $PM_{2.5}$ exposure based on 4-year average concentrations and liver cancer incidence on both the Main Islands and Penghu Islets. Additionally, the authors examined whether there was evidence of a direct or indirect effect of long-term $PM_{2.5}$ exposure on serum alanine transaminase (ALT) levels, which is a marker of chronic liver tissue inflammation, and subsequently liver cancer incidence. During the course of the study, new cases of liver cancer were identified during follow-up by pathological examination. Between the two locations, the distribution of $PM_{2.5}$ concentrations varied dramatically with an IQR of 0.73 μ/m^3 on the Penghu Islets and 13.1 μg/m^3 the Main Islands, therefore, results are not standardized to a 5 μg/m^3 increase, which as noted previously

is the convention for the rest of the epidemiologic study results for $PM_{2.5}$ presented within this section. Based on an IQR increase, Pan et al. (2016) reported a HR = 1.22 (95% CI: 1.02, 1.47) on the Penghu Islets and HR = 1.21 (95% CI: 0.95, 1.52) on the Main Islands. In the mediation analysis, there was evidence of an indirect effect of long-term $PM_{2.5}$ exposure on liver cancer incidence through elevated ALT levels, as well as some evidence of a potential direct effect. This initial evidence of a potential association between long-term $PM_{2.5}$ exposure and liver cancer is consistent with the results of Pedersen et al. (2017) in the ESCAPE study, which used a more rigorous exposure assignment method than Pan et al. (2016). Focusing on the two cohorts conducted in Denmark and Italy that reported $PM_{2.5}$ concentrations, the authors reported a positive association with new liver cancer cases diagnosed during follow-up (HR = 1.34 [95% CI: 0.76, 2.35]), but the 95% confidence intervals were large.

10.2.5.2.4 Leukemia

The association between long-term $PM_{2.5}$ exposure and incident leukemia was examined in cohorts consisting of children in Italy (Badaloni et al., 2013) and the U.S. (Heck et al., 2013), and adults in Canada (Winters et al., 2015). Badaloni et al. (2013) in the SETIL study (i.e., Study on the aetiology of lymphohematopoietic malignancies in children), examined incident leukemia in children ≤10 years of age in a case-control study. In quartile analyses using the entire cohort, as well as analyses limited to children between the ages of 0−4, and those children that did not change residence during the course of the study, the authors observed no evidence of an association between long-term $PM_{2.5}$ exposure and incident leukemia. Heck et al. (2013) examined incident childhood cancer (ages <6 years) from the California Cancer Registry. In a case-control study, the authors did not observe clear evidence of an association between $PM_{2.5}$ and acute lymphoblastic leukemia (OR = 1.06 [95% CI: 0.95, 1.18], n = 397) no evidence of an association with acute myeloid leukemia (OR = 0.90 [95% CI: 0.70, 1.16], n = 82). A similar result was observed by Winters et al. (2015) also using a case-control study design to examine incident leukemia in adults across Canadian provinces (except for Quebec and New Brunswick). The authors reported no evidence of an association between long-term $PM_{2.5}$ exposure and incident leukemia as well as chronic lymphocytic leukemia.

10.2.5.2.5 Multiple Cancers

Although most of the studies that examine long-term $PM_{2.5}$ exposure and cancer focused on specific cancer types, a few studies examined a number of different cancer types. Wong et al. (2016) in a study conducted in Hong Kong examined mortality attributed to a variety of cancers as detailed in Table 10-6. Within this study $PM_{2.5}$ concentrations were much higher (mean = 33.7 $\mu g/m^3$) compared to the other studies evaluated in this section. Across mortality outcomes attributed to cancer types, the authors observed strong positive associations (i.e., in terms of magnitude and precision) for all malignant,

all digestive organs, and female genital cancers with HRs ranging from 1.10 to 1.32. There was no evidence of an association for male genital, urinary, or lymphohematopoietic cancer mortality.

Whereas Wong et al. (2016) focused on cancer mortality, Heck et al. (2013) and Lavigne et al. (2017) examined incident childhood cancers in California and Ontario, Canada, respectively. Heck et al. (2013) in a case-control study, examined associations between $PM_{2.5}$ exposure during the entire pregnancy and childhood cancer (ages <6 years). There was not clear evidence of an association between $PM_{2.5}$ and cancer risk for any of the cancer sites except for retinoblastoma (OR = 1.33 [95% CI: 1.06, 1.67], n = 87). Lavigne et al. (2017) also examined multiple childhood cancers, but included cancer diagnoses up to age 14. In addition to examining exposures during the entire pregnancy, the authors also examined trimester specific exposures as well as those during the first year of life. Focusing on cancers with greater than 200 cases during the study period (i.e., acute lymphoblastic leukemia, astrocytoma, and Wilms tumor) the authors reported evidence of a number of positive associations across trimesters, the entire pregnancy, and the first year of life for each of these cancers, but 95% confidence intervals were large for all except astrocytoma (HR = 1.80 [95% CI: 1.09, 2.92] for the 1st trimester and HR = 1.68 [95% CI: 1.00, 2.89] for the entire pregnancy). These results are inconsistent with Heck et al. (2013), which also examined astrocytoma and found no evidence of an association with $PM_{2.5}$ exposure during the entire pregnancy.

10.2.5.2.6 Summary

Compared to the 2009 PM ISA, more recent studies have examined associations between long-term $PM_{2.5}$ exposure and cancer incidence and mortality beyond the respiratory system. Across the cancers examined, which includes breast cancer, brain cancer, liver cancer, and leukemia there is inconsistent evidence of an association with long-term $PM_{2.5}$ exposure. In addition to the cancers evaluated within this section, there are a few individual studies that examined ovarian cancer (Hung et al., 2012) and bladder cancer (Liu et al., 2009). Collectively, there are a small number of studies that examined other cancers and this evidence does not clearly depict an association between long-term $PM_{2.5}$ and cancer in other sites.

10.2.5.3 Cancer Survival

The majority of air pollution epidemiologic studies focusing on cancer tend to examine whether long-term exposures are associated with cancer incidence or mortality, as previously detailed within this section. Recently, studies have also examined whether exposure to air pollutants, such as $PM_{2.5}$, can have a detrimental impact on cancer survival. Study characteristics for the studies that examined cancer survival in response to long-term $PM_{2.5}$ exposures are detailed in Table 10-7.

Table 10-7 Study specific details and $PM_{2.5}$ concentrations from recent studies that examined cancer survival.

Study Location, Years, Data	Population/Cancer	Mean Concentration µg/m^3	Exposure Assessment	Results
†Xu et al. [e]<10 µg/m^3 was the referent.

†Studies published since the 2009 PM ISA.

Xu et al. (2013) and Eckel et al. (2016) examined cancer survival by focusing on both the influence of $PM_{2.5}$ concentrations on overall survival as well as the risk of death or cancer-related death in individuals with any respiratory cancer or lung cancer, respectively. Xu et al. (2013) focused on two areas representative of high (Los Angeles) and low (Honolulu) $PM_{2.5}$ concentrations, while Eckel et al. (2016) focused specifically on whether lung cancer cases resided in areas with higher and lower $PM_{2.5}$ concentrations. In Xu et al. (2013) and Eckel et al. (2016), cancer survival was found to decrease in areas with higher $PM_{2.5}$ concentrations, which was further supported by the categorical analysis conducted in Xu et al. (2013) where there was evidence of increased risk of mortality among people with cancer when comparing the higher polluted area (Los Angeles) with the lower polluted area (Honolulu). Additionally, in analyses in both studies where $PM_{2.5}$ was included as a continuous variable there was evidence of positive associations between long-term $PM_{2.5}$ exposure and overall mortality and respiratory/lung cancer mortality (Table 10-7).

Additional evidence indicating a potential relationship between cancer survival and long-term $PM_{2.5}$ concentrations was provided by studies conducted in California that examined breast cancer survival (Hu et al., 2013) and liver cancer survival (Deng et al., 2017). Hu et al. (2013) reported evidence of higher breast cancer mortality in cases living in counties with higher $PM_{2.5}$ concentrations as well as a high overall risk of breast cancer death. In the study of liver cancer survival, Deng et al. (2017) observed an overall increase in the risk of all-cause mortality as well as evidence that mortality risk increases in liver cancer patients as $PM_{2.5}$ concentrations increased (Table 10-7). Both of these studies provide initial evidence that although long-term $PM_{2.5}$ exposure has not been associated with breast cancer incidence, and only a few studies have examined liver cancer incidence (see Section 10.2.5.3), underlying cancer may contribute to increasing the risk of death after diagnosis.

In addition to examining overall cancer survival, Eckel et al. (2016), Hu et al. (2013), and Deng et al. (2017) examined whether the stage of cancer diagnosis modified survival. In each of these studies there was initial evidence, through categorical analyses, of a nonlinear relationship between $PM_{2.5}$ exposure and cancer survival, where patients with less advanced cancer at diagnosis (i.e., local or regional) had lower survival if they resided in locations with higher compared to lower $PM_{2.5}$ concentrations (Table 10-7). This pattern of associations was not observed in patients diagnosed with distant (i.e., late) stage cancer likely due to the advanced stage of cancer and overall lower survival rate. Collectively, these studies provide initial evidence that exposure to long-term $PM_{2.5}$ concentrations may contribute to reduced cancer survival. However, caution is warranted in the interpretation of the results from these studies because they are all conducted in one location, California.

10.2.6 Associations between $PM_{2.5}$ Sources and Components and Cancer

As characterized throughout this ISA, PM itself is a complex mixture consisting of numerous individual components derived from a variety of sources (see Chapter 2). It has been well characterized over the years that a number of these individual components are mutagenic, and carcinogenic (Claxton and Woodall, 2007; Claxton et al., 2004). The 2009 PM ISA noted that animal toxicological studies did not focus on specific PM size fractions, but instead emissions from various sources. The 2009 PM ISA concluded that ambient urban PM, emissions from wood smoke and coal combustion, and gasoline exhaust and DE are mutagenic, while PAHs are genotoxic. This conclusion is consistent with previous studies that demonstrated ambient PM and PM from specific combustion sources are mutagenic and genotoxic (U.S. EPA, 2009). Recent studies examined specific $PM_{2.5}$ components and in some cases related those components to specific sources to evaluate whether individual $PM_{2.5}$ components or sources are more closely related to lung cancer mortality and incidence, as well as DNA methylation, than $PM_{2.5}$ mass.

Thurston et al. (2013) in the National Particle Component and Toxicity (NPACT) study, which focused on the ACS-CPS II cohort, examined associations with individual $PM_{2.5}$ components and lung cancer mortality, and only observed evidence of positive associations with Se, a coal combustion tracer, and S. The authors used factor analysis and absolute principal component analysis (APCA) to identify source-related groupings and source categories, respectively. The results of the factor and source-apportionment analyses, which found positive associations with a Coal Combustion source, are consistent with the single-pollutant $PM_{2.5}$ component analyses. Thurston et al. (2013) did not observe evidence of clear associations with lung cancer mortality for any of the other source categories or tracer elements. (quantitative results not presented). The ESCAPE study also examined associations between long-term exposure to $PM_{2.5}$ components and lung cancer mortality. Raaschou-Nielsen et al. (2016) examined associations with eight $PM_{2.5}$ components (Cu, Fe, K, Ni, S, Si, V, and Zn) estimated using LUR methods. Positive associations were observed with all $PM_{2.5}$ components (with the exception of V), albeit with wide confidence intervals, with HR ranging from 1.02 to 1.34 for an IQR increase in $PM_{2.5}$ component concentrations.

Instead of focusing on traditional $PM_{2.5}$ components, Weichenthal et al. (2016) in the CanCHEC cohort examined the association between $PM_{2.5}$ oxidative burden (the product of mass concentration and oxidative potential) and lung cancer mortality. Regional time-weighted $PM_{2.5}$ (2012−2013) average oxidative potential was assessed according to the ability of filter extracts to deplete glutathione and ascorbate in synthetic respiratory tract lining fluid (percent depletion/μg). As detailed previously, there was a positive association with $PM_{2.5}$ mass that was found to be stronger in terms of magnitude and precision when using the glutathione-related $PM_{2.5}$ oxidative burden exposure metric (HR per IQR change in $PM_{2.5}$ and glutathione-related oxidative potential = 1.12 [95% CI: 1.05, 1.19]). There was no

association with ascorbate-related $PM_{2.5}$ oxidative burden (HR per IQR change in $PM_{2.5}$ and ascorbate-related oxidative potential = 0.97 [95% CI: 0.93, 1.01]).

In addition to studies that examined associations between $PM_{2.5}$ components and lung cancer mortality and incidence, a few studies examined whether specific $PM_{2.5}$ components are more strongly related to DNA methylation. Madrigano et al. (2011) within the Normative Aging Study discussed previously, also examined associations between individual $PM_{2.5}$ components and DNA methylation. In addition to $PM_{2.5}$ mass, the authors also observed associations for a reduction in methylation when examining BC and SO_4, particularly in LINE-1, but 95% confidence intervals were large. Additional studies conducted within the Beijing Truck Driver Air Pollution Study cohort detailed previously, also examined the influence of individual $PM_{2.5}$ components on DNA methylation. Hou et al. (2014) examined whether specific $PM_{2.5}$ components (i.e., Al, Ca, Fe, K, S, Si, Ti, and Zn) altered methylation of the same tandem repeats examined in Guo et al. (2014). The authors observed when examining associations for 10% increase in each component that there was evidence of an increase in SATα methylation for S in office workers and in NBL2 methylation for Si and Ca in truck drivers. However, Hou et al. (2014) did not examine components that comprised a larger percentage of $PM_{2.5}$ mass. For example, both Si and Ca represented less than 2 and 1% of the total $PM_{2.5}$ mass exposure for truck drivers and office workers, respectively. The authors reported no evidence of associations with other elemental components (Al, K, Ti, Fe, and Zn) or a difference in the methylation of the tandem repeat D4Z4. Sanchez-Guerra et al. (2015) also examined the Beijing Truck Driver Air Pollution Study cohort, but as detailed above focused on methylation of both 5mC and 5hmC. The authors did not report any evidence of an increase in 5hmC for the components examined in Hou et al. (2014) as well as BC.

Overall, the studies that examined associations between long-term exposure to $PM_{2.5}$ components and sources and lung cancer mortality are consistent with previous evaluations that have indicated that components and sources related to combustion activities are mutagenic and genotoxic and provide biological plausibility for PM-related lung cancer incidence and mortality (U.S. EPA, 2009). Additionally, initial evidence indicates that $PM_{2.5}$ oxidative potential may be an important metric to consider in the future. The limited number of studies that examined associations between exposure to $PM_{2.5}$ components and DNA methylation as well as the limited number of components examined, did not provide consistent evidence that any one component altered DNA methylation.

10.2.7 Summary and Causality Determination

It has been well characterized in toxicological studies that ambient air has mutagenic properties (Claxton et al., 2004) and that extracts of PM from ambient air have carcinogenic properties (Claxton and Woodall, 2007). However, at the completion of the 2009 PM ISA, little information was available from studies employing specific PM size fractions, such as $PM_{2.5}$, or inhalation exposure. The evidence indicating that PM was both a mutagen and carcinogen was supported by epidemiologic evidence of

primarily positive associations in studies of lung cancer mortality, with limited evidence for lung cancer incidence and other cancers. Since the 2009 PM ISA, a larger number of cohort studies using both traditional and more refined exposure assignment approaches provide evidence that primarily consists of positive associations between $PM_{2.5}$ exposure and both lung cancer mortality and lung cancer incidence, which is supported by subset analyses focusing on never smokers. In addition, $PM_{2.5}$ exhibits several key characteristics of carcinogens (Smith et al., 2016), as shown in toxicological studies demonstrating genotoxic effects, oxidative stress, electrophilicity, and epigenetic alterations, with supportive evidence provided by epidemiologic studies. Furthermore, $PM_{2.5}$ has been shown to act as a tumor promoter in a rodent model of urethane-initiated carcinogenesis. This biological plausibility, in combination with the epidemiologic evidence for $PM_{2.5}$ and lung cancer mortality and incidence, contributes to the conclusion of a likely to be causal relationship between long-term $PM_{2.5}$ exposure and cancer. This section describes the evaluation of evidence for cancer, with respect to the causality determination for long-term exposure to $PM_{2.5}$ using the framework described in Table II of the Preamble to the ISAs (U.S. EPA, 2015). The key evidence, as it relates to the causal framework, is summarized in Table 6-34.

Table 10-8 Summary of evidence for a likely to be causal relationship between long-term $PM_{2.5}$ exposure and cancer.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Consistent epidemiologic evidence from multiple, high quality studies at relevant $PM_{2.5}$ concentrations	Increases in lung cancer mortality and incidence in cohort studies conducted in the U.S., Canada, Europe, and Asia. Supported by subset analyses reporting positive associations in never smokers.	Section 10.2.5.1.1 Figure 10-3	Annual: U.S. and Canada: 6.3−23.6 Europe: 6.6−31.0 Asia: 33.7 Table 10-4
Limited epidemiologic evidence from copollutant models for an independent $PM_{2.5}$ association	Potential copollutant confounding for lung cancer mortality and incidence examined in a few studies with initial evidence that associations remained robust in models with O_3, with more limited information for other gaseous pollutants and particle size fractions.	Section 10.2.5.1.3	—
Epidemiologic evidence supports a linear, no-threshold concentration-response (C-R) relationship	Recent multicity studies conducted in the U.S., Canada, and Europe provide evidence of a linear, no-threshold C-R relationship for annual $PM_{2.5}$ concentrations observed within the U.S., but extensive systematic evaluations of alternatives to linearity have not been conducted.	Section 10.2.5.1.4	—

Table 10 8 (Continued): Summary of evidence for a likely to be causal relationship between long term $PM_{2.5}$ exposure and cancer.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Extensive evidence for biological plausibility	Experimental studies provide evidence for oxidative stress in human subjects while in vivo inhalation studies in rodents indicate oxidative DNA damage and methylation of a tumor suppressor gene promotor in the lung, upregulation of enzymes involved in biotransformation, and tumor promotion in a model of urethane-induced tumor initiation. Studies conducted in vitro show formation of DNA adducts, DNA damage, formation of micronuclei, oxidative stress, altered methylation of repetitive elements and miRNAs, increased telomerase activity, mutagenicity, and increased metastatic potential. Additionally, there is supporting epidemiologic evidence for micronuclei formation.	Liu et al. (2015) Soberanes et al. (2012) Yoshizaki et al. (2016) Cangerana Pereira et al. (2011) Section 10.2.1 Section 10.2.2 Section 10.2.3 Section 10.2.4 Section 10.2.5	238 µg/m^3 100−120 µg/m^3 594 µg/m^3 17.66 µg/m^3
Coherence of cancer-related effects across disciplines	Epidemiologic evidence that is coherent with experimental evidence for DNA adduct formation, DNA damage, cytogenetic effects, and altered DNA methylation	Li et al. (2014); Rossner et al. (2013b) Chu et al. (2015) Rossner et al. (2011) O'Callaghan-Gordo et al. (2015) Section 10.2.3	115.4 12.0−78.9 68.4−146.6 26.1−28.4 14.4

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Table I and Table II of the Preamble to the ISAs (U.S. EPA, 2015).

[b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

Experimental and epidemiologic studies provide evidence indicating the potential role of $PM_{2.5}$ exposure in genotoxicity through an examination of cancer-related biomarkers, such as mutagenicity, DNA damage, and cytogenetic endpoints. Decades of research has laid a foundation supporting the mutagenic potential of PM. It has been clearly demonstrated in the Ames *Salmonella*/mammalian-microsome mutagenicity assay that PM contains mutagenic agents (Section 10.2.2.1). Although mutagenicity does not necessarily equate to carcinogenicity, the ability of PM to elicit mutations provides support for observations of an association with lung cancer mortality and incidence in epidemiologic studies. Both in vitro and in vivo toxicological studies indicate the potential for $PM_{2.5}$ exposure to result in DNA damage (Section 10.2.2.2), which is supported by limited evidence from epidemiologic panel studies (Chu et al., 2015) and findings of oxidative stress in a controlled human exposure study (Liu et al., 2015). When examining cytogenetic effects, a limited number of epidemiologic

and toxicological studies provides coherence for micronuclei formation and chromosomal abnormalities (Section 10.2.2.3). Additionally, there was limited evidence for differential expression of genes that may be relevant to cancer pathogenesis. Across scientific disciplines, a broad array of biomarkers of genotoxicity were examined, which complicates the assessment of whether there was evidence for coherence of effects, but overall these studies provide some evidence of a relationship between $PM_{2.5}$ exposure and genotoxicity. Similarly, experimental and epidemiologic studies that examined epigenetic effects indicate changes in methylation, both hyper- and hypomethylation, globally as well as in some specific genomic sites, providing some support for $PM_{2.5}$ exposure contributing to genomic instability (Section 10.2.3). Toxicological evidence that the promoter region of a tumor suppressor gene, p16, was methylated in lung tissue as a result of inhalation exposure to $PM_{2.5}$ is consistent with one of the hallmarks of cancer (Hanahan and Weinberg, 2000); (Hanahan and Weinberg, 2011), i.e., the evading of growth suppressors (Section 10.2.3.1).

The experimental and epidemiologic evidence for genotoxicity and mutagenicity, as well as epigenetic effects, provides biological plausibility for a relationship between exposure to $PM_{2.5}$ and cancer development. In addition, $PM_{2.5}$ exposure enhanced tumor formation in an animal model of urethane-induced tumor initiation (Cangerana Pereira et al., 2011). This study supports a role for $PM_{2.5}$ exposure in tumor promotion, which is a measure of carcinogenic potential. Further substantiating the link between $PM_{2.5}$ exposure and cancer development are epidemiologic studies demonstrating primarily consistent positive associations between long-term $PM_{2.5}$ exposure and lung cancer mortality and incidence across studies using different exposure assignment methods (Section 10.2.5.1). The evidence of $PM_{2.5}$-related lung cancer mortality and incidence is further supported by a number of studies that examined associations by smoking status and reported generally positive associations in never smokers. Across studies, potential confounding by smoking status and exposure to SHS was adequately controlled through either direct measures of smoking status or by using proxy measures to adjust for smoking. Of those studies that did not report evidence of a positive association, only Lipsett et al. (2011) in the CTS cohort examined associations by smoking status for lung cancer mortality and also reported evidence of a positive, albeit imprecise, association in never smokers. A number of the studies focusing on lung cancer incidence examined associations by histological subtype, which allows for an assessment of adenocarcinoma, the only lung cancer subtype found in nonsmokers. Across studies that examined histological subtypes, there was some evidence of positive associations with adenocarcinomas, but associations were imprecise (i.e., wide confidence intervals) and often also observed for other subtypes.

A limited number of recent lung cancer mortality and incidence studies conducted analyses to assess potential copollutant confounding and reported that $PM_{2.5}$ associations were relatively unchanged in models with O_3. However, there was a more limited assessment of potential copollutant confounding by other gaseous pollutants and particle size fractions (Section 10.2.5.1.3). Recent assessments of the C-R relationship between long-term $PM_{2.5}$ exposure and lung cancer mortality and incidence provide evidence of a linear, no-threshold relationship, specifically at concentrations representative of the lowest cut-point examined in studies, 9−11.8 $\mu g/m^3$, and where analyses of the C-R curve depict a widening of confidence

intervals, ≈6 μg/m^3. However, in assessing the C-R relationship, epidemiologic studies have not conducted empirical evaluations of potential alternatives to linearity (Section 10.2.5.1.4).

In addition to lung cancer mortality and incidence, a number of recent studies examined cancers of other sites including breast cancer, brain cancer, liver cancer, and leukemia. Across the studies, the evidence does not clearly depict an association with other types of cancers (Section 10.2.5.2). However, emerging evidence examining cancer survival in people diagnosed with various stages of different types of cancers including respiratory cancer, lung cancer, breast cancer, and liver cancer indicate that long-term $PM_{2.5}$ exposure may contribute to reduced cancer survival, particularly in individuals with less advanced cancer diagnoses (Section 10.2.5.3).

Collectively, experimental and epidemiologic studies provide evidence for a relationship between $PM_{2.5}$ exposure and genotoxicity, epigenetic effects, and carcinogenic potential. Uncertainties exist due to the lack of consistency in specific cancer-related biomarkers associated with $PM_{2.5}$ exposure across both experimental and epidemiologic studies, however $PM_{2.5}$ exhibits several characteristics of carcinogens. This provides biological plausibility for $PM_{2.5}$ exposure contributing to cancer development. **Overall, the combination of this evidence is sufficient to conclude that a causal relationship is likely to exist between long-term $PM_{2.5}$ exposure and cancer**.

10.3 $PM_{10-2.5}$ Exposure and Cancer

The 2009 PM ISA concluded that the overall body of evidence was "inadequate to assess the relationship between long-term $PM_{10-2.5}$ exposures and cancer" (U.S. EPA, 2009).[77] This conclusion was based on the lack of epidemiologic studies that examined $PM_{10-2.5}$ exposure and cancer in both the 2004 PM AQCD and the 2009 PM ISA.

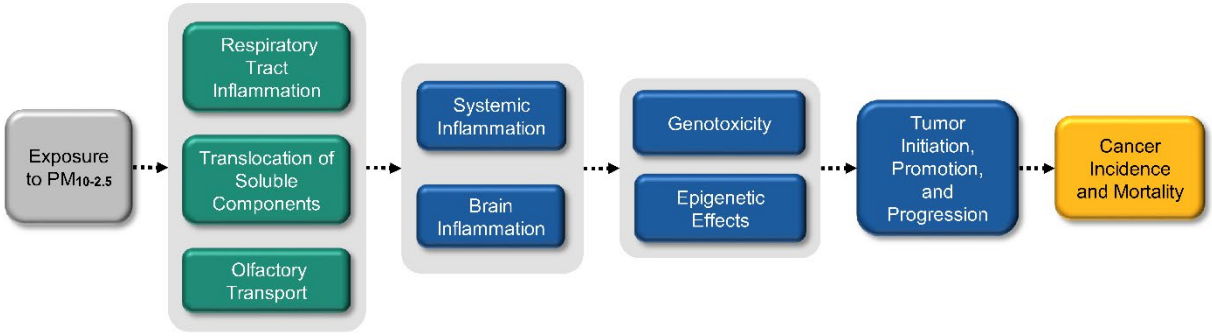
Consistent with the 2009 PM ISA, there remains a limited number of both experimental and epidemiologic studies that examined $PM_{10-2.5}$ exposure and whether it can lead to mutagenicity, genotoxicity, and carcinogenicity, as well as to cancer mortality. Although there is some evidence that $PM_{10-2.5}$ exposure can lead to changes in cancer-related biomarkers, there is a lack of epidemiologic evidence to support the continuum of effects to cancer incidence and mortality. The following sections evaluate studies published since completion of the 2009 PM ISA that focus on the mutagenicity, genotoxicity, and capability of long-term exposures to $PM_{10-2.5}$ to induce epigenetic changes all of which may contribute to cancer incidence and mortality.

[77] As detailed in the Preface, risk estimates are for a 5 μg/m^3 increase in annual $PM_{10-2.5}$ concentrations unless otherwise noted.

10.3.1 Biological Plausibility

This section describes biological pathways that potentially underlie the development of cancer resulting from exposure to $PM_{10-2.5}$. Figure 10-8 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" exposure to $PM_{10-2.5}$ may lead to the development of cancer contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 10.3.

Once $PM_{10-2.5}$ deposits in the respiratory tract, it may be retained, cleared, or solubilized (see Chapter 4). $PM_{10-2.5}$ and its soluble components may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate ROS and this capacity is termed "oxidative potential". Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see Chapter 4). Immune system responses due to the presence of particles in the interstitial space may contribute to chronic health effects. Inflammatory mediators may diffuse from the respiratory tract into the systemic circulation and lead to inflammation in extrapulmonary compartments (see Chapter 6). Although $PM_{10-2.5}$ is mostly insoluble, it may contain some soluble components such as endotoxin and metals. Soluble components of $PM_{10-2.5}$ may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments. A fraction of $PM_{10-2.5}$ may deposit on the olfactory epithelium. Soluble components of $PM_{10-2.5}$ may be transported via the olfactory nerve to the olfactory bulb of the brain. The extent to which translocation into the systemic circulation or transport to the olfactory bulb occurs is currently uncertain. For further discussion of translocation and olfactory transport, see Chapter 4. The potential contribution of olfactory transport to brain inflammation or to upregulation of gene expression in the brain is discussed in Chapter 8.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 10-8 Potential biological pathways for the development of cancer following exposure to $PM_{10-2.5}$.

Evidence is accumulating that exposure to $PM_{10-2.5}$ may lead to carcinogenesis by a genotoxic pathway that may result in mutational events or chromosomal alterations. Carcinogenesis due to dysregulated growth may follow. Compared with $PM_{2.5}$, there is less evidence that $PM_{10-2.5}$ exhibits characteristics of carcinogens (Smith et al., 2016). However, exposure to $PM_{10-2.5}$ has been shown to result in genotoxic effects and to induce oxidative stress. Currently, epidemiologic evidence is limited to studies linking $PM_{10-2.5}$ exposure to lung cancer incidence. Evidence for these pathways and cancer-related biomarkers is described below.

Genotoxicity

Genotoxicity may occur as a result of DNA damage and subsequent introduction of mutations into the genome, and as a result of cytogenetic effects at the level of the chromosome. $PM_{10-2.5}$ exposure is associated with mutagenicity, DNA damage, and cytogenetic effects. Oxidative stress is one mechanisms involved in genotoxicity resulting from $PM_{2.5}$ exposure.

Mutations are considered biomarkers of early biological effect (Demetriou et al., 2012). Indirect evidence is provided by the Ames *Salmonella*/mammalian-microsome mutagenicity assay in one study. It can identify the presence of species that can result in mutations as the result of direct interactions with DNA as well as those that require metabolic activation to elicit genotoxicity. As the most widely accepted theory of cancer etiology is the accumulation of mutations in critical genes, the presence of mutagens within PM provides biological plausibility for observations made in epidemiological studies. While this assay has several technical limitations and is criticized due to its use of bacteria as a model species, four

decades of published results from this assay have clearly demonstrated the presence of mutagenic agents in PM collected from ambient air (U.S. EPA, 2009). A new study published since the 2009 PM ISA provides evidence to support mutagenicity resulting from $PM_{10–2.5}$ exposure (Kawanaka et al., 2008).

DNA damage is a biomarker of genotoxicity (Demarini, 2013). Evidence of DNA damage following $PM_{10–2.5}$ exposure was found using the comet assay in in vitro toxicological studies (Jalava et al., 2015; Wessels et al., 2010). The identification of oxidized DNA bases suggests a role for oxidative stress in the DNA lesions. These oxidized DNA nucleobases are considered a biomarker of exposure (Demetriou et al., 2012). Exposure to PM can result in oxidative stress either through the direct generation of ROS, or indirectly, through the induction of inflammation. Other in vitro studies demonstrated an increase in ROS production as a result of exposure to $PM_{10–2.5}$ (Section 10.3.2). A study in human subjects also found increased oxidized DNA bases in urine in association with $PM_{10–2.5}$ exposure (Liu et al., 2015). The presence of oxidative stress-mediated DNA lesions and adducts can lead to the introduction of fixed mutations into the genome after incorrect repair of the damaged base or replication past the base by low fidelity DNA polymerases. The potential for oxidative stress to result in mutagenesis is underscored by the DNA repair mechanisms that have evolved to protect the genome from mutagenesis caused by these lesions.

Cytogenetic effects, such as micronuclei formation and chromosomal aberrations, are biomarkers of genotoxicity (Demarini, 2013). Micronuclei are nuclei formed as a result of chromosomal damage, while chromosomal aberrations are modifications of the normal chromosome complement (Demetriou et al., 2012). Epidemiologic studies provide supportive evidence of micronuclei formation in association with $PM_{10–2.5}$ exposure (O'Callaghan-Gordo et al., 2015).

Summary of Biological Plausibility

As described here, there is one proposed pathway by which exposure to $PM_{10–2.5}$ may lead to the development of cancer. It involves genotoxicity, including DNA damage that may result in mutational events and cytogenetic effects that may result in effects at the level of the chromosome. While experimental studies in animals and humans contribute most of the evidence of upstream events, epidemiologic studies found associations between exposure to $PM_{10–2.5}$ and micronuclei formation. This proposed pathway provides biological plausibility for epidemiologic results of cancer incidence and mortality and will be used to inform a causality determination, which is discussed later in the chapter (Section 10.3.4).

10.3.2 Genotoxicity

In the 2009 PM ISA, there were a limited number of epidemiologic studies that examined molecular and cellular markers often associated with cancer, which includes both DNA damage and

cytogenetic effects. No studies specifically examined the effects of exposure to $PM_{10-2.5}$. Recent experimental and epidemiologic studies provide a limited body of evidence for genotoxicity due to $PM_{10-2.5}$ exposure.

10.3.2.1 Toxicological Evidence

Very few studies evaluating the genotoxicity and carcinogenicity of $PM_{10-2.5}$ have been published since the 2009 PM ISA. More common are reports detailing the effects in response to PM_{10}. However, as given the scope of the current ISA, only studies detailing the effects of $PM_{10-2.5}$ exposure are summarized here. While the Ames *Salmonella*/mammalian-microsome mutagenicity test was the most common method for analysis of genotoxicity in response to $PM_{2.5}$, the use of human cell culture and other in vitro assays were the primary method for the study of $PM_{10-2.5}$. No new studies published since the 2009 PM ISA that evaluated endpoints related to epigenetic changes in response to ambient air $PM_{10-2.5}$ exposure were identified.

Kawanaka et al. (2008) investigated the mutagenicity of roadside PM organic extracts from Saitama City, Japan. Using a cascade impactor, 12 fractions of varying aerodynamic diameters were collected including $PM_{10-2.5}$ (<0.12, 0.12−0.20, 0.20−0.30, 0.30−0.50, 0.70−1.2, 1.2−2.1, 2.1−3.5, 3.5−5.2, 5.2−7.8, 7.8−11, >11 μm). The authors used the *Salmonella* assay to determine the mutagenic activity of each fraction as well as GC/NCI/MS/MS and known quantities of select nitroaromatic compounds to determine the mass contribution of those compounds to the total PM collected and to estimate the contribution of each species to the total mutagenicity, respectively. Using this approach, it was reported that quantity of nitro-PAHs per unit mass in the ultrafine fraction was greater than that of $PM_{2.5}$ or $PM_{10-2.5}$. In addition, the authors determined that mutagenicity per unit mass of $PM_{10-2.5}$ was less than that of UFP (both TA98 and YG1024 S. Typhimurium strains) and that, of the six nitroaromatic compounds evaluated, the contribution to mutagenic activity calculated was greatest for 1,8-dinitropyrene in all three fractions of PM extracts evaluated. As a result of the variability of the *Salmonella* assay as well as incomplete details regarding the statistical analysis of the data collected, it is difficult to calculate definitive values for these contributions.

Jalava et al. (2015) used the alkaline comet assay to measure DNA damage after exposure to PM suspensions in mouse macrophages (RAW 264.7). They evaluated four size fractions including $PM_{10-2.5}$ collected at Nanjing University in China. The authors observed an increase in damage compared with controls ($p \leq 0.05$), however, the increase was observed only following exposure to the PM suspension of greatest concentration.

Wessels et al. (2010) also characterized the effect of exposure to $PM_{10-2.5}$ in cultured human cells. To represent and compare diverse PM mixture profiles, the authors collected PM from four locations including a rural location and three urban locations that varied in the extent to which vehicle traffic would contribute to the PM mixture sampled. Five size fractions were collected and that with the largest

particles comprised PM with aerodynamic diameters in the range of 3−7 μm. To evaluate the genotoxicity of aqueous PM suspensions, human lung carcinoma epithelial cells (A549) were cultured and used in the formamido-pyrimidine-glycosylase (fpg)-modified comet assay. No differences were observed in the amount of DNA damage induced after exposure to $PM_{10–2.5}$ collected from any of the urban locations compared to that of equal mass collected from the rural location. This is in contrast to the smaller diameter fractions collected for which more DNA damage was observed for several of the urban roadside PM suspension exposures compared to PM collected from the rural site. In addition, the authors determined that, after adjusting for sampling site, the amount of DNA damage measured in response to exposure to different particle size fractions was similar.

Mirowsky et al. (2015), investigated the effects of exposure to aqueous suspensions of both soluble and insoluble material from $PM_{10–2.5}$ as well as $PM_{2.5}$ collected at two rural and three urban sites in California. Using cultured human pulmonary microvasculature endothelial cells (HPMEC-ST11.6R), they measured ROS with 2′,7′-dichlorofluorescein diacetate (DCFH-DA). DCFH-DA, after removal of the acetate groups by cellular esterases, can be oxidized to highly fluorescent DCF that can then be used to quantify the amount of intracellular ROS. The results identified two variables. That is, both the size fraction and location at which the PM was collected can affect the amount of intracellular ROS generated after exposure to aqueous PM suspension. Suspensions from $PM_{10–2.5}$ collected at urban sites were characterized by greater ROS activity than those from $PM_{2.5}$ collected at the same sites ($p < 0.001$). The same disparity was not observed, however, between the $PM_{10–2.5}$ and $PM_{2.5}$ suspensions from the rural sites as the ROS activity generated by both was similar. When comparing the same size fractions between urban and rural sites, greater ROS activity was observed in experiments with $PM_{10–2.5}$ from the urban sites than $PM_{10–2.5}$ collected at the rural sites, while there was not any difference reported between sites for the $PM_{2.5}$ suspensions (*p*-value not provided).

In the same study, Mirowsky et al. (2015) also used oropharyngeal aspiration to assess the response to aqueous PM suspension exposure in mice (FVB/N). As inflammation and ROS generated by infiltrating polymorphonuclear cells (PMNs) has also been proposed as a pathway that may result in genotoxicity, the authors compared the effect of exposure on the percent of PMNs in lavage fluid for the various sampling locations and PM size fractions. With the exception of one rural location, the increase in percentage of PMNs engendered by exposure to $PM_{10–2.5}$ suspensions was greater than that after exposure to $PM_{2.5}$ ($p < 0.001$).

Gordon et al. (2013) also used the DCFA-FA assay to assess intracellular ROS after exposure to PM. The authors exposed BEAS-2B and HBEpC cells to suspensions of size-fractionated PM from ambient air collected from five diverse sampling locations across the U.S. The PM size fractions collected were described as $PM_{2.5–0.2}$, $PM_{10–2.5}$, and $PM_{0.2}$. Similar to several other findings already highlighted, the authors reported variation in ROS production as a result of sampling site, season, and particle size and noted that exposure to $PM_{10–2.5}$ resulted in ROS production that was less than that of the ultrafine fraction, but greater than that of $PM_{2.5}$ on an equal mass exposure when sampling locations were combined.

10.3.2.2 Evidence from Controlled Human Exposure Studies

A controlled human exposure study by Liu et al. (2015) measured MDA in blood and urine and 8-oxo-dG in urine. The former is a lipid peroxidation product capable of reacting with DNA bases, while the latter is excreted after oxidized dGTP molecules in cellular dNTP pools used for nuclear and mitochondrial DNA replication throughout the cell are acted upon by MTH1 followed by 8-oxo-dGMPase in the process of dNTP pool sanitization. In this single-blind randomized crossover study, nonsmoking adults were exposed for 130 minutes to $PM_{10–2.5}$, $PM_{2.5}$, and UFP CAPs drawn from a downtown street in Toronto, Canada. Participant blood and urine were collected before exposure and after exposure at two-time points (1 hour, 21 hour). A positive association was observed between urinary 8-oxo-dG concentration and concentration of $PM_{10–2.5}$ ($p < 0.1$) at 1-hour post-exposure. Urinary creatinine was used to normalize biomarker concentrations. No association was observed between blood MDA concentration and $PM_{10–2.5}$ concentration.

10.3.2.3 Epidemiologic Evidence

In the Rhea cohort previously detailed in Section 10.2.2, the frequency of micronuclei was examined in 136 mother-child pairs in Crete, Greece (O'Callaghan-Gordo et al., 2015). Within the study, $PM_{10–2.5}$ concentrations (median = 22.5 μg/m^3) were estimated by taking the difference between PM_{10} and $PM_{2.5}$ from monitors at the same location. The pattern of associations observed for exposure to $PM_{10–2.5}$ and micronuclei frequency was similar to that for $PM_{2.5}$, but the magnitude of the association was smaller for $PM_{10–2.5}$. Overall, there was some evidence of a higher micronuclei frequency in maternal blood for an exposure over the entire pregnancy (RR = 1.14 [95% CI 0.94−1.38]), but no evidence of an association for cord blood (RR = 0.96 [95% CI 0.79−1.17]) (O'Callaghan-Gordo et al., 2015). Similar to $PM_{2.5}$, when stratifying by smoking status, an association larger in magnitude was observed in smoking mothers (RR = 1.4 [95% CI: 0.94, 2.1]) compared to nonsmokers (RR = 1.1 [95% CI: 0.86, 1.3]), but 95% confidence intervals crossed the null for both. Additionally, there was evidence that the association between $PM_{10–2.5}$ and micronuclei frequency was increased among women with a lower intake of vitamin C during pregnancy (i.e., <85 ng/day).

10.3.2.4 Summary of Genotoxicity

Evidence that $PM_{10–2.5}$ exposure induces mutagenicity, DNA damage, oxidative DNA damage, and oxidative stress is provided by a limited number of in vitro animal toxicological studies and a single controlled human exposure study. Liu et al. (2015) found oxidative DNA damage following an approximately 2-hour exposure of human subjects to $PM_{10–2.5}$, with rapid but transient increase in a urine biomarker. The tissue source of this marker cannot be discerned so it is unclear where in the body the

DNA damage occurred. Additionally, an epidemiologic study reported evidence of increased micronuclei formation in relation to $PM_{10-2.5}$ exposure (O'Callaghan-Gordo et al., 2015).

10.3.3 Cancer Incidence and Mortality

10.3.3.1 Lung Cancer

At the completion of the 2009 PM ISA, no epidemiologic studies had been conducted that examined the association between long-term $PM_{10-2.5}$ exposure and cancer. Since then, a few studies have examined cancer, but overall the body of evidence is small. As detailed previously, additional studies have examined the overall relationship between long-term exposure to PM and lung cancer by focusing on PM_{10}. However, these PM_{10} studies are not the focus of this evaluation due to their inability to attribute any cancer effects to a specific PM size fraction, such as $PM_{10-2.5}$. A full list of PM_{10} and lung cancer mortality and incidence studies are available at: https://hero.epa.gov/hero/particulate-matter.

10.3.3.1.1 Lung Cancer Incidence

Recent studies that examined the association between long-term $PM_{10-2.5}$ exposure and lung cancer are limited to studies of lung cancer incidence. There were no epidemiologic studies that examined exposures to $PM_{10-2.5}$ and lung cancer mortality. In addition to examining $PM_{10-2.5}$, the studies by Raaschou-Nielsen et al. (2013) in the ESCAPE study and Puett et al. (2014) in the NHS cohort also examined associations with $PM_{2.5}$ as detailed in Section 10.2.2. Study specific details including $PM_{10-2.5}$ concentrations, study population, and exposure assignment approach are presented in Table 10-9.

Table 10-9 Study specific details and $PM_{10-2.5}$ concentrations from recent studies that examined lung cancer incidence.

Study Years	Cohort Location	Years Air Quality/Follow-up	Events/Population	Mean Concentration µg/m³	Exposure Assessment
Lung cancer incidence					
North America					
†Puett et al. (2014)	NHS (U.S.)	$PM_{10-2.5}$: 1988−2007 Follow-up: 1994−2010	Cases: 2,155 Pop: 103,650	8.5[a]	GIS-based spatiotemporal model to each residential address as detailed in Yanosky et al. (2008); $PM_{10-2.5}$ calculated by subtracting monthly PM_{10} and $PM_{2.5}$ estimates
Europe					
†Raaschou-Nielsen et al. (2013)	ESCAPE (Europe)	$PM_{10-2.5}$: 2008−2011 Follow-up: 1990s[b]	Cases: 2,095 Pop: 312,944	Across sites: 4.0−20.8	LUR at geocoded addresses as detailed in Eeftens et al. (2012a); $PM_{10-2.5}$ calculated as the difference between PM_{10} and $PM_{2.5}$ estimates

[a]Overall 72-mo cumulative average $PM_{10-2.5}$ concentration.

[b]Only 14 or the 17 cohorts were examined for lung cancer, of the cohorts examined initial recruitment started generally in the 1990s with an average follow-up time of 12.8 years.

†Studies published since the 2009 PM ISA.

Both Raaschou-Nielsen et al. (2013) and Puett et al. (2014) estimated $PM_{10-2.5}$ concentrations by subtracting the difference between LUR estimates of PM_{10} and $PM_{2.5}$. As detailed in Section 3.3.2.3, estimating $PM_{10-2.5}$ concentrations by subtracting modeled PM_{10} and $PM_{2.5}$ estimates do not result in the same issues that could occur when subtracting PM_{10} and $PM_{2.5}$ concentrations from collocated monitors. In the ESCAPE study Raaschou-Nielsen et al. (2013) reported an imprecise positive association with $PM_{10-2.5}$ (HR = 1.09 [95% CI 0.88, 1.33]). Puett et al. (2014) in the NHS cohort, which consisted only of women, also reported an imprecise positive association with lung cancer incidence (HR = 1.02 [95% CI: 0.96, 1.10]). Compared to the $PM_{2.5}$ results in both studies, the magnitude of the association was similar for Puett et al. (2014), but for Raaschou-Nielsen et al. (2013) the $PM_{2.5}$ effect was larger in magnitude and more indicative of a relationship with lung cancer incidence.

For Raaschou-Nielsen et al. (2013), unlike the analysis of $PM_{2.5}$ that examined a subset of the cohort that did not change residence during follow-up, a sensitivity analysis was not conducted for $PM_{10-2.5}$ to assess the potential influence of exposure measurement error. Additionally, an analysis by

histological cancer subtype was not conducted for $PM_{10–2.5}$. However, Puett et al. (2014) in the NHS cohort examined associations by smoking status and histological cancer subtype. The authors observed that the association between long-term $PM_{10–2.5}$ exposure and lung cancer incidence was larger in magnitude among never smokers, but 95% confidence intervals were still large (HR = 1.05 [95% CI: 0.86, 1.30]). When focusing specifically on those lung cancer cases defined as adenocarcinoma in the full cohort, the magnitude of the association was larger (HR = 1.11 [95% CI: 0.94, 1.30]) than that observed when focusing on all lung cancer incidence cases.

10.3.3.2 Other Cancers

A few recent studies have examined associations between long-term $PM_{10–2.5}$ exposure and cancer incidence and mortality beyond the respiratory system. This includes individual studies examining breast cancer (Hart et al., 2016) and liver cancer (Pedersen et al., 2017) that reported positive associations, (HR = 1.03 [95% CI: 0.96, 1.10]) and (HR ranging from 1.26−1.86 depending on the ESCAPE cohort), respectively, but with large 95% confidence intervals. Collectively, there are a limited number of studies that examined other cancers and this evidence does not clearly depict an association between long-term $PM_{10–2.5}$ and other cancer sites.

10.3.3.3 Summary

Overall, there is limited evidence of a positive association between long-term $PM_{10–2.5}$ exposure and lung cancer incidence, with no studies examining lung cancer mortality. In both studies that examined lung cancer incidence, $PM_{10–2.5}$ concentrations were estimated by taking the difference between PM_{10} and $PM_{2.5}$ estimates, but these estimates were derived from an LUR model (see Section 3.3.2.3). A few recent studies examined associations with cancers in other sites, but the limited number of studies prevents a full assessment of the relationship between long-term $PM_{10–2.5}$ exposure and cancers in other sites.

10.3.4 Summary and Causality Determination

It has been well characterized in toxicological studies that ambient air has mutagenic properties (Claxton et al., 2004) and that extracts of PM from ambient air have carcinogenic properties (Claxton and Woodall, 2007). However, at the completion of the 2009 PM ISA, little information was available from studies employing specific PM size fractions, such as $PM_{10–2.5}$, or inhalation exposure. Since the 2009 PM ISA, the assessment of long-term $PM_{10–2.5}$ exposure and cancer remains limited with a few recent epidemiologic studies of large and diverse cohorts providing evidence of imprecise positive associations of $PM_{10–2.5}$ with lung cancer incidence. However, uncertainty remains with respect to exposure measurement error due to the methods employed to estimate $PM_{10–2.5}$ concentrations (Section 3.3.2.3),

specifically the use of $PM_{10-2.5}$ predictions that have not been validated by monitored $PM_{10-2.5}$ concentrations. Experimental studies are more limited in number compared with the evaluation of $PM_{2.5}$ and consist of a controlled human exposure study and several in vitro animal toxicological studies demonstrating DNA damage, oxidative stress, and mutagenicity. $PM_{10-2.5}$ exhibits two key characteristics of carcinogens (Smith et al., 2016), as shown in experimental studies demonstrating genotoxic effects and oxidative stress, providing some biological plausibility for epidemiologic findings. The small number of epidemiologic and experimental studies. along with the uncertainty with respect to exposure measurement error, contribute to the determination of the relationship between long-term $PM_{10-2.5}$ exposure and cancer using the framework described in Table II of the Preamble to the ISAs (U.S. EPA, 2015). The key evidence, as it relates to the causal framework, is summarized in Table 10-10. **Overall, the evidence is suggestive of, but not sufficient to infer, a causal relationship between long-term $PM_{10-2.5}$ exposure and cancer**.

Table 10-10 Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between long-term $PM_{10-2.5}$ exposure and cancer.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{10-2.5}$ Concentrations Associated with Effects[c]
A limited body of epidemiologic evidence at relevant $PM_{10-2.5}$ concentrations	Positive, but imprecise, increases in lung cancer incidence in a few studies conducted in North America and Europe.	Section 10.3.3.1	U.S.: 8.5 Europe: 4.0−20.8
Uncertainty regarding exposure measurement error	$PM_{10-2.5}$ concentrations estimated by taking the difference between LUR modeled PM_{10} and $PM_{2.5}$ concentrations. Uncertainty remains because $PM_{10-2.5}$ predictions are not validated by monitored $PM_{10-2.5}$ concentrations although PM_{10} and $PM_{2.5}$ LUR model predictions are validated.	Section 3.3.2.3	
Evidence for biological plausibility	Experimental studies provide evidence for oxidative DNA damage in human subjects and DNA damage, oxidative stress, and mutagenicity in vitro. Additional epidemiologic evidence supports micronuclei formation.	Liu et al. (2015) Section 10.3.2.1 O'Callaghan-Gordo et al. (2015)	213 µg/m^3

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Table I and Table II of the Preamble to the ISAs (U.S. EPA, 2015).

[b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

[c]Describes the $PM_{10-2.5}$ concentrations with which the evidence is substantiated.

10.4 UFP Exposure and Cancer

The 2009 PM ISA concluded that the overall body of evidence was "inadequate to assess the relationship between long-term UFP exposures and cancer." This conclusion was based on the lack of epidemiologic studies that examined UFP exposure and cancer in both the 2004 PM AQCD and the 2009 PM ISA.

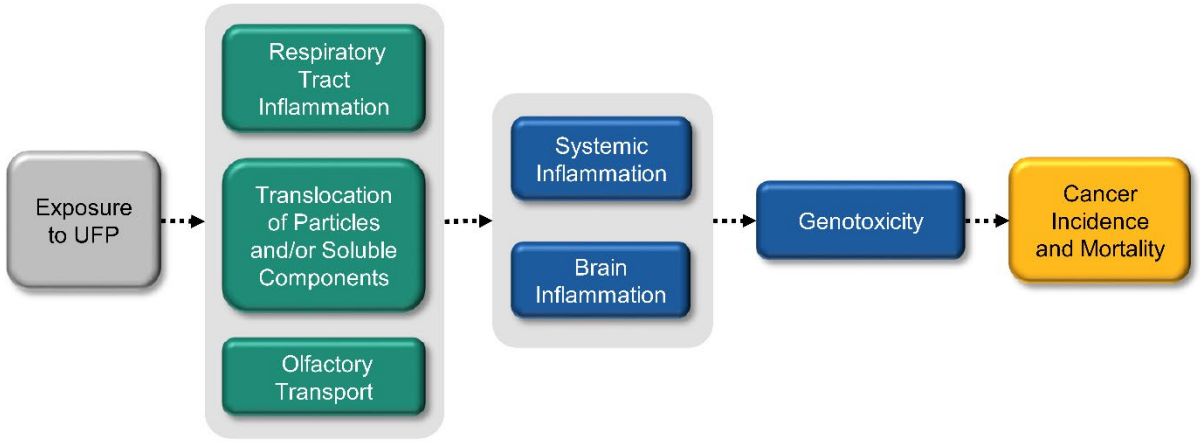
Consistent with the 2009 PM ISA, there remains a limited number of both experimental and epidemiologic studies that examined UFP exposure and whether it can lead to mutagenicity, genotoxicity, and carcinogenicity, as well as to cancer mortality, with no studies of lung cancer incidence or mortality. Although there is some evidence that UFP exposure can lead to changes in cancer-related biomarkers, there is a lack of epidemiologic evidence to support the continuum of effects to cancer incidence and mortality. The following sections evaluate studies published since completion of the 2009 PM ISA that focus on the mutagenicity and, genotoxicity of long-term exposures to UFP, which may contribute to cancer incidence and mortality.

10.4.1 Biological Plausibility

This section describes biological pathways that potentially underlie the development of cancer resulting from exposure to UFP. Figure 10-9 graphically depicts the proposed pathways as a continuum of upstream events, connected by arrows, that may lead to downstream events observed in epidemiologic studies. This discussion of "how" exposure to UFP may lead to the development of cancer contributes to an understanding of the biological plausibility of epidemiologic results evaluated later in Section 0.

Once UFP deposits in the respiratory tract, it may be retained, cleared, or solubilized (see Chapter 4). UFP and its soluble components may interact with cells in the respiratory tract, such as epithelial cells, inflammatory cells, and sensory nerve cells. One way in which this may occur is through reduction-oxidative (redox) reactions. As discussed in Section 2.3.3, PM may generate ROS and this capacity is termed "oxidative potential". Furthermore, cells in the respiratory tract may respond to the presence of PM by generating ROS. Further discussion of these redox reactions, which may contribute to oxidative stress, is found in Section 5.1.1 of the 2009 PM ISA (U.S. EPA, 2009). In addition, poorly soluble particles may translocate to the interstitial space beneath the respiratory epithelium and accumulate in the lymph nodes (see Chapter 4). Immune system responses due to the presence of particles in the interstitial space may contribute to chronic health effects. Inflammatory mediators may diffuse from the respiratory tract into the systemic circulation and lead to inflammation in extrapulmonary compartments (see Chapter 6). UFP and its soluble components may translocate into the systemic circulation and contribute to inflammatory or other processes in extrapulmonary compartments. A fraction of UFP may deposit on the olfactory epithelium. UFP and its soluble components may be transported via the olfactory nerve to the olfactory bulb of the brain. The extent to which translocation

into the systemic circulation or transport to the olfactory bulb occurs is currently uncertain. For further discussion of translocation and olfactory transport, see Chapter 4. The potential contribution of olfactory transport to brain inflammation or to upregulation of gene expression in the brain is discussed in Chapter 8.



Note: The boxes above represent the effects for which there is experimental or epidemiologic evidence, and the dotted arrows indicate a proposed relationship between those effects. Shading around multiple boxes denotes relationships between groups of upstream and downstream effects. Progression of effects is depicted from left to right and color-coded (gray, exposure; green, initial event; blue, intermediate event; orange, apical event). Here, apical events generally reflect results of epidemiologic studies, which often observe effects at the population level. Epidemiologic evidence may also contribute to upstream boxes. When there are gaps in the evidence, there are complementary gaps in the figure and the accompanying text below.

Figure 10-9 Potential biological pathways for the development of cancer following exposure to UFP.

Evidence is accumulating that exposure to UFP may lead to carcinogenesis by a genotoxic pathway that may result in mutational events or chromosomal alterations. Carcinogenesis due to dysregulated growth may follow. Compared with $PM_{2.5}$, there is less evidence that UFP exhibits characteristics of carcinogens (Smith et al., 2016). However, exposure to UFP resulted in genotoxic effects and oxidative stress. In addition, exposure to UFP induced genes involved in PAH biotransformation, indicating that UFP contained electrophilic species. Currently there are no epidemiologic studies evaluating the relationship between exposure to UFP and lung cancer, although breast cancer incidence has been studied. Evidence for these pathways and for cancer-related biomarkers is described below.

Genotoxicity

Genotoxicity may occur as a result of DNA damage and subsequent introduction of mutations into the genome, and as a result of cytogenetic effects at the level of the chromosome. UFP exposure is associated with mutagenicity and DNA damage. Mechanisms involved in genotoxicity resulting from UFP exposure include oxidative stress and biotransformation.

Mutations are considered biomarkers of early biological effect (Demetriou et al., 2012). Indirect evidence is provided by the Ames *Salmonella*/mammalian-microsome mutagenicity assay. It can identify the presence of species that can result in mutations as the result of direct interactions with DNA as well as those that require metabolic activation to elicit genotoxicity. As the most widely accepted theory of cancer etiology is the accumulation of mutations in critical genes, the presence of mutagens within PM provides biological plausibility for observations made in epidemiological studies. While this assay has several technical limitations and is criticized due to its use of bacteria as a model species, four decades of published results from this assay have clearly demonstrated the presence of mutagenic agents in PM collected from ambient air (U.S. EPA, 2009). A new study published since the 2009 PM ISA provides evidence to support mutagenicity resulting from UFP exposure (Kawanaka et al., 2008).

DNA damage is a biomarker of genotoxicity (Demarini, 2013). Evidence of DNA damage resulting from exposure to UFP was found using the comet assay which measures single and double DNA strand breaks in vitro (Jalava et al., 2015). The identification of oxidized DNA bases suggests a role for oxidative stress in the DNA lesions. These oxidized DNA nucleobases are considered a biomarker of exposure (Demetriou et al., 2012). Exposure to PM can result in oxidative stress either through the direct generation of reactive oxygen species (ROS), or indirectly, through the induction of inflammation. An in vitro study demonstrated an increase in ROS production as a result of exposure to UFP (Gordon et al., 2013). Studies in human subjects found increased oxidized DNA bases in urine (Liu et al., 2015) and evidence of DNA damage in peripheral blood mononuclear cells (Hemmingsen et al., 2015) in association with UFP exposure. The presence of oxidative stress-mediated DNA lesions and adducts can lead to the introduction of fixed mutations into the genome after incorrect repair of the damaged base or replication past the base by low fidelity DNA polymerases. The potential for oxidative stress to result in mutagenesis is underscored by the DNA repair mechanisms that have evolved to protect the genome from mutagenesis caused by these lesions.

Evidence that genes participating in PAH biotransformation are upregulated as a result of exposure to UFP is provided by an in vitro study (Borgie et al., 2015a). Biotransformation via Cyp1A1 may result in the production of PAH metabolites capable of reacting with DNA to form bulky DNA adducts. As in the case of oxidative stress mediated DNA adducts, when DNA repair of bulky adducts is absent or ineffective, mutational events may occur.

Summary of Biological Plausibility

As described here, there is one proposed pathway by which exposure to UFP may lead to the development of cancer. It involves genotoxicity, including DNA damage that may result in mutational events. Experimental studies in animals and humans contribute all of the evidence of upstream events. This proposed pathway provides biological plausibility for epidemiologic results of cancer incidence and mortality and will be used to inform a causality determination, which is discussed later in the section (Section 10.4.4).

10.4.2 Genotoxicity

10.4.2.1 Toxicological Evidence

Similar to $PM_{10-2.5}$ exposure, very few studies have been published since the 2009 ISA that describe effects relevant to genotoxicity resulting from exposure to UFP.

Kawanaka et al. (2008) investigated the mutagenicity of roadside PM organic extracts from Saitama City, Japan. Using a cascade impactor, 12 fractions of varying aerodynamic diameters were collected including an ultrafine fraction (<0.12). The authors used the *Salmonella* assay to determine the mutagenic activity of each fraction as well as GC/NCI/MS/MS and known quantities of select nitroaromatic compounds to determine the mass contribution of those compounds to the total PM collected and to estimate the contribution of each species to the total mutagenicity, respectively. Using this approach, it was reported that the quantity of nitro-PAHs per unit mass in the ultrafine fraction was greater than that of $PM_{10-2.5}$ or $PM_{2.5}$. In addition, the authors determined that mutagenicity per unit mass of UFP was greater than that of the other two PM size fractions in both TA98 and YG1024 S. Typhimurium strains. Of the six nitroaromatic compounds evaluated, the contribution to mutagenic activity calculated was greatest for 1,8-dinitropyrene in all three fractions of PM extracts evaluated. As a result of the variability of the *Salmonella* assay as well as incomplete details regarding the statistical analysis of the data collected, it is difficult to calculate definitive values for these contributions.

Jalava et al. (2015), as discussed earlier in the $PM_{2.5}$ and $PM_{10-2.5}$ sections, used the alkaline comet assay to measure DNA damage after exposure to PM suspensions in mouse macrophages (RAW 264.7). They evaluated four size fractions including a near ultrafine fraction described as $PM_{0.2}$ collected at Nanjing University in China. Similar to the increase observed after exposure to $PM_{10-2.5}$, the authors observed an increase in damage compared with controls ($p \leq 0.05$), however, the increase was only observed following exposure to the PM suspension of greatest concentration.

Gordon et al. (2013) measured intracellular ROS in BEAS-2B and HBEpC cells using the DCFH-DA assay after exposure to ambient UFP, as well as $PM_{10-2.5}$ and $PM_{2.5}$ size fractions collected

from five diverse sampling locations across the U.S. Similar to several other findings already highlighted, the authors reported variation in ROS production as a result of sampling site, season, and particle size and noted that exposure to the ultrafine fraction resulted in ROS production that was greater than that of both $PM_{10–2.5}$ and $PM_{2.5}$ on an equal mass exposure when sampling locations were combined.

Borgie et al. (2015a) collected ambient PM with aerodynamic diameters near those considered ultrafine (<0.3 μm) from an urban and rural location near Beirut, Lebanon and exposed cultured BEAS-2B cells to extracted organic material from the collected PM as well as intact PM suspension. The authors measured AhR, ARNT, AhRR, CYP1A1, CYP1B1, and NQO1 gene expression. They reported that, generally, an increase in CYP1A1, CYP1B1, and AhRR ($p < 0.05$) mRNA expression was observed compared to controls for both urban and rural sites. These findings are consistent with the results from their study that evaluated $PM_{2.5}$ (Borgie et al., 2015b). In that study, they also observed increases in CYP1A1, CYP1B1, and AhRR gene expression after exposure to $PM_{2.5–0.3}$ suspensions. Notably, while the current study by Borgie et al. (2015a) reported that increases in gene expression were observed for cells exposed to both EOM and aqueous suspensions, the increases in gene expression were generally greater after exposure to EOM compared with PM suspension ($p > 0.05$). This is consistent with the findings noted by Turner et al. (2015).

10.4.2.2 Evidence from Controlled Human Exposure Studies

Controlled human exposure studies have also evaluated various markers relevant to DNA damage. Hemmingsen et al. (2015) identified an association between combined DNA strand breaks and FPG sensitive sites in peripheral blood mononuclear cells and total particle number concentration using a mixed effects analysis ($p = 0.016$). These measures were representative of nonoxidative and oxidative DNA damage, respectively. In contrast, no evidence of oxidative stress or DNA damage was found in relation to $PM_{2.5}$ concentration. As described in Section 10.2.2.2, this controlled, cross-over, repeated measures human exposure study was carried out in central Copenhagen, Denmark in overweight, older adults who were exposed for 5 hours in chambers with and without high efficiency particulate adsorption filters.

A controlled human exposure study by Liu et al. (2015) measured MDA in blood and urine and 8-oxo-dG in urine. The former is a lipid peroxidation product capable of reacting with DNA bases, while the latter is excreted after oxidized dGTP molecules in cellular dNTP pools used for nuclear and mitochondrial DNA replication throughout the cell are acted upon by MTH1 followed by 8-oxo-dGMPase in the process of dNTP pool sanitization. In this single-blind randomized crossover study, nonsmoking adults were exposed for 130 minutes to $PM_{10–2.5}$, $PM_{2.5}$, and UFP CAPs drawn from a downtown street in Toronto, Canada. Participant blood and urine were collected before exposure and after exposure at two time points (1 hour, 21 hour). A positive association was observed between urinary 8-oxo-dG concentration and UFP concentration ($p < 0.05$) at 1-hour post-exposure. Urinary creatinine

was used to normalize biomarker concentrations. No association was observed between blood MDA concentration and concentration of UFP.

10.4.2.3 Summary of Genotoxicity

Evidence that UFP exposure induces mutagenicity, DNA damage, oxidative DNA damage, oxidative stress, and upregulation of enzymes involved in biotransformation is provided by a limited number of in vitro animal toxicological studies and two controlled human exposure study. Hemmingsen et al. (2015) identified an association between DNA damage in peripheral blood mononuclear cells and total particle number concentration. Liu et al. (2015) found oxidative DNA damage following an approximately 2-hour exposure of human subjects to UFP, with rapid but transient increase in a marker in urine. The tissue source of this marker cannot be discerned so it is unclear where in the body the DNA damage occurred. There were no epidemiologic studies that evaluated genotoxicity and carcinogenicity in relation to UFP exposure.

10.4.3 Cancer Incidence and Mortality

At the completion of the 2009 PM ISA, there were no studies that examined the association between long-term UFP exposure and lung cancer incidence or mortality or cancers in other sites. The only recent study that has focused on cancer and UFPs is a study conducted by Goldberg et al. (2017) in Montreal, Canada that examined postmenopausal breast cancer incidence. In a population-based, case-control study where UFP exposures from a LUR were assigned at geocoded addresses or centroids of postal codes the authors reported no evidence of an association in a model controlling for all individual-level covariates (OR = 1.02 [95% CI: 0.93, 1.13] for a 3,461.9 cm^{-3} increase in UFPs).

10.4.4 Summary and Causality Determination

It has been well characterized in toxicological studies that ambient air has mutagenic properties (Claxton et al., 2004) and that extracts of PM from ambient air have carcinogenic properties (Claxton and Woodall, 2007). However, at the completion of the 2009 PM ISA, little information was available from studies employing specific PM size fractions, such as UFP, or inhalation exposure. Since the 2009 PM ISA, a single epidemiologic study evaluated breast cancer incidence and found no evidence to support this outcome. Furthermore, no epidemiologic studies evaluated lung cancer in association with UFP exposure. Experimental studies are few in number and consist of a few controlled human exposure studies and in vitro animal toxicological studies. UFP exhibits two key characteristics of carcinogens (Smith et al., 2016) by demonstrating genotoxic effects and oxidative stress in experimental studies. While there is some biological plausibility for exposure to UFP and cancer, there is a lack of epidemiologic evidence of

cancer incidence or mortality. Additionally, there is uncertainty in the spatial variability of long-term UFP exposures, which is compounded by the relatively sparse UFP monitoring data in the U.S. This section describes the evaluation of evidence for cancer, with respect to the causality determination for long-term exposures to UFP using the framework described in Table II of the Preamble to the ISAs (U.S. EPA, 2015). The key evidence, as it relates to the causal framework, is summarized in Table 10-11. **Overall, the evidence is inadequate to infer the presence or absence of a causal relationship between long-term UFP exposure and cancer**.

Table 10-11 Summary of evidence that is inadequate to infer the presence or absence of a causal relationship between long-term UFP exposure and cancer.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	UFP Concentrations Associated with Effects[c]
Lack of epidemiologic evidence at relevant UFP concentrations	Assessment of cancer limited to a study of breast cancer that reported no evidence of an association	Section 10.4.3	—
Uncertainty regarding exposure measurement error	Limited data on UFP concentrations over time and the spatial variability of UFP concentrations across urban areas	Section 2.5.1.1.5 Section 2.5.1.2.4 Section 2.5.2.2.3 Section 3.4.5	
Limited evidence for biological plausibility	Experimental studies provide evidence for oxidative DNA damage in human subjects while in vitro studies indicate DNA damage, oxidative stress, upregulation of enzymes involved in biotransformation, and mutagenicity	Hemmingsen et al. (2015) Liu et al. (2015) Kawanaka et al. (2008) Section 10.4.2	23,000/cm^2 136 µg/m^3

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Table I and Table II of the Preamble to the ISAs (U.S. EPA, 2015).

[b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

[c]Describes the UFP concentrations with which the evidence is substantiated.

CHAPTER 11 MORTALITY

Summary of Causality Determinations for Short- and Long-Term PM Exposure and Total (Nonaccidental) Mortality

This chapter characterizes the scientific evidence that supports causality determinations for short- and long-term PM exposure and total mortality. The types of studies evaluated within this chapter are consistent with the overall scope of the ISA as detailed in the Preface (see Section P.3.1). In assessing the overall evidence, strengths and limitations of individual studies were evaluated based on scientific considerations detailed in the Appendix. More details on the causal framework used to reach these conclusions are included in the Preamble to the ISA (U.S. EPA, 2015b).

Size Fraction	Causality Determination
Short-term exposure	
$PM_{2.5}$	Causal
$PM_{10-2.5}$	Suggestive of, but not sufficient to infer
UFP	Inadequate
Long-term exposure	
$PM_{2.5}$	Causal
$PM_{10-2.5}$	Suggestive of, but not sufficient to infer
UFP	Inadequate

11.1 Short-Term $PM_{2.5}$ Exposure and Total Mortality

The 2009 Integrated Science Assessment for Particulate Matter (hereafter 2009 PM ISA) concluded that "a causal relationship exists between short-term exposure to $PM_{2.5}$ and mortality" (U.S. EPA, 2009).[78] This conclusion was based on the evaluation of both multi- and single-city studies that further supported the consistent positive associations between short-term $PM_{2.5}$ exposure and mortality (i.e., total [nonaccidental] mortality) observed in the 2004 PM AQCD, with associations for total (nonaccidental) mortality ranging from 0.29% (Dominici et al., 2007) to 1.2% (Franklin et al., 2007). These associations were strongest, in terms of magnitude and precision, primarily at lags within the range of 0−1 days. Although an examination of the potential confounding effects of gaseous copollutants was

[78] As detailed in the Preface, risk estimates are for a 10 μg/m^3 increase in 24-hour avg $PM_{2.5}$ concentrations, unless otherwise noted.

limited in the studies evaluated in the 2009 PM ISA, evidence from single-city studies evaluated in the 2004 PM AQCD indicated that gaseous copollutants have minimal effect on the $PM_{2.5}$-mortality relationship. The evaluation of cause-specific mortality found that risk estimates were larger in magnitude, but also had larger confidence intervals, for respiratory mortality compared to cardiovascular mortality. Although the largest mortality risk estimates were for respiratory mortality, the interpretation of the results was complicated by the limited coherence from studies of respiratory morbidity. However, the evidence from studies of cardiovascular morbidity provided both coherence and biological plausibility for the relationship between short-term $PM_{2.5}$ exposure and cardiovascular mortality.

The multicity studies evaluated in the 2009 PM ISA provided initial information with respect to seasonal patterns of associations and city-to-city heterogeneity in $PM_{2.5}$-mortality risk estimates along with potential factors that may explain some of this heterogeneity. An evaluation of $PM_{2.5}$-mortality risk estimates by season indicated that associations tend to be largest in magnitude during the spring. Additionally, multicity studies demonstrated a regional pattern in associations with the magnitude being larger in the Eastern U.S., but also indicated that nationally, and even within a region, there are differences among city-specific $PM_{2.5}$-mortality risk estimates. Although not systematically considered across the studies evaluated in the 2009 PM ISA, several studies examined factors that provided some evidence that may explain the heterogeneity in $PM_{2.5}$-mortality risk estimates observed both within and across studies, including exposure factors (e.g., air-conditioning use), demographic differences, and $PM_{2.5}$ composition.

An evaluation of the concentration-response (C-R) relationship and whether a threshold exists was limited to multicity studies of PM_{10}. Collectively, the multicity studies that examined the C-R relationship between short-term PM_{10} exposure and mortality reported evidence of a linear, no-threshold relationship. However, some studies that also examined the C-R relationship for individual cities provided initial evidence indicating potential city-to-city differences in the shape of the C-R curve.

In addition to examining the association between short-term $PM_{2.5}$ exposures and mortality with a focus on PM mass, a few multicity studies examined whether specific $PM_{2.5}$ components modified the $PM_{2.5}$-mortality relationship while other studies focused on examining whether individual $PM_{2.5}$ components or PM sources were more strongly associated with mortality than $PM_{2.5}$ mass. In many cases, the evaluation of $PM_{2.5}$ components was limited due to the rather sparse temporal data coverage as a result of the every 3rd or 6th day sampling schedule of monitors. Collectively, these studies did not provide evidence that any one component or source is more strongly associated with mortality, which is consistent with the larger body of literature that examined the relationship between $PM_{2.5}$ components and sources and other health effects (U.S. EPA, 2009).

As detailed in the Preface, the focus of this section is on the evaluation of recently published studies that directly address policy-relevant issues, i.e., those studies where mean 24-hour average concentrations are less than 20 $\mu g/m^3$ across all cities or where at least half of the cities have mean 24-hour average concentrations less than 20 $\mu g/m^3$. Additionally, consistent with previous ISAs, this

section focuses primarily on multicity studies because they examine the association between short-term $PM_{2.5}$ exposure and a health effect over a large geographic area that consists of diverse atmospheric conditions and population demographics, using a consistent statistical methodology, which avoids the potential publication bias often associated with single-city studies (U.S. EPA, 2008). However, where applicable single-city studies, as well as multicity studies with mean 24-hour average concentrations greater than 20 $\mu g/m^3$, are evaluated when they: encompass a long study-duration; examine whether a specific population or lifestage may be at increased risk of $PM_{2.5}$-related mortality (see Chapter 12); or further characterize the relationship between short-term $PM_{2.5}$ exposure and mortality (e.g., copollutant analyses) not represented in the multicity studies with mean 24-hour average concentrations less than 20 $\mu g/m^3$ (U.S. EPA, 2016, 2015a). Other recent studies that do not fit the criteria mentioned above are not the focus of this section, and are available at: https://hero.epa.gov/hero/particulate-matter.

The following sections provide a brief overview of the consistent, positive associations observed in recent studies of mortality and short-term $PM_{2.5}$ exposures, with the main focus on assessing the degree to which these studies further characterize the relationship between short-term $PM_{2.5}$ exposure and mortality detailed in the 2009 PM ISA (U.S. EPA, 2009). The multicity, as well as single-city studies, discussed throughout this section, along with study-specific details and air quality characteristics are highlighted in Table 11-1 and represent those studies that attempt to further characterize the $PM_{2.5}$-mortality evidence by examining: potential confounding (i.e., copollutants and seasonal/temporal trends); effect modification (e.g., stressors, pollutants, season); geographic heterogeneity in associations; shape of the C-R relationship and related issues (e.g., threshold, lag structure of associations); and the relationship between $PM_{2.5}$ components and sources and mortality.

[a]Multicity studies included in the 2004 PM AQCD.

[b]Median concentrations.

[c]Range of mean concentrations across all cities.

[d]Only had data for all-cause mortality including accidental mortalities, focused analyses on total (nonaccidental) mortality.

[e]Due to the sparsity of data for year 2000, it was excluded from the main analysis.

[f]Young et al. (2017) only reported average $PM_{2.5}$ concentrations for each year and not an average across all years; therefore this range represents the minimum and maximum concentration reported in any year across all air basins.

[g]Only 4 of the 5 cities had $PM_{2.5}$ data.

[h]Stafoggia et al. (2017) did not report quantitative estimates for cardiovascular and respiratory mortality.

†Studies published since the 2009 PM ISA.

11.1.1 Biological Plausibility for Short-Term $PM_{2.5}$ Exposure and Total (Nonaccidental) Mortality

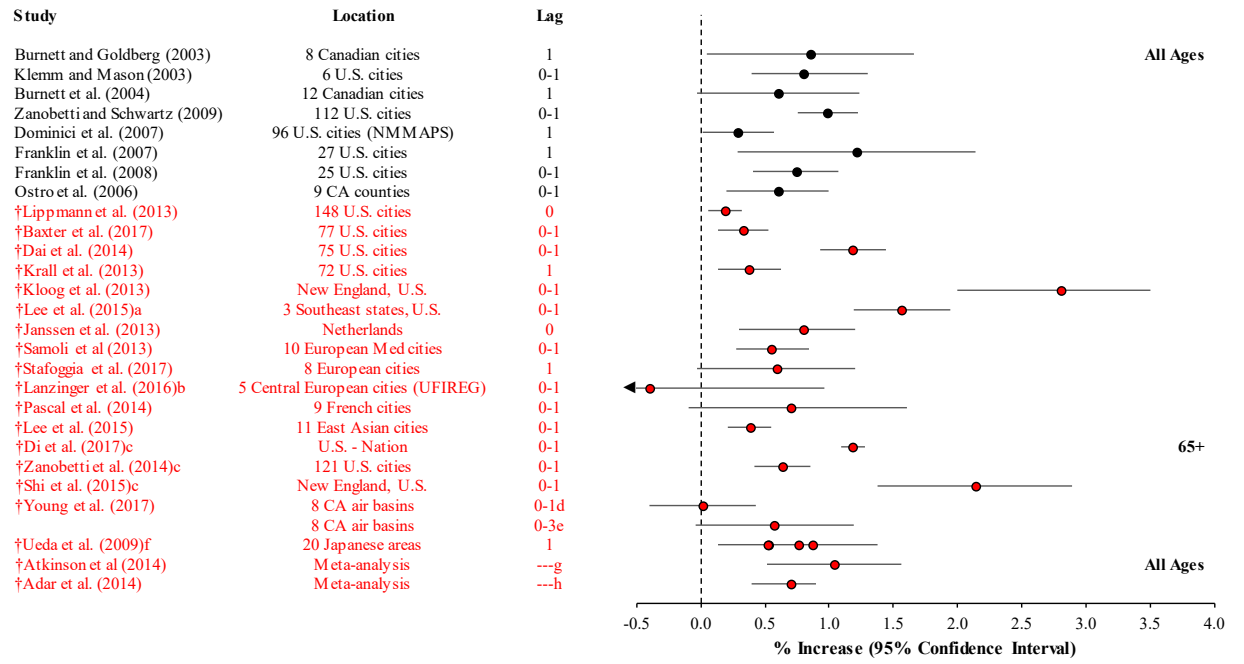
The preceding chapters characterized evidence related to evaluating the biological plausibility by which short-term $PM_{2.5}$ exposure may lead to the morbidity effects that are the largest contributors to total (nonaccidental) mortality, specifically cardiovascular and respiratory morbidity (Section 6.1.1 and Section 5.1.1, respectively). This evidence is derived from animal toxicological, controlled human exposure, and epidemiologic studies. Section 6.1.1 outlines the available evidence for plausible mechanisms by which inhalation exposure to $PM_{2.5}$ could progress from initial events to endpoints relevant to the cardiovascular system and to population outcomes such as emergency department (ED) visits and hospital admissions due to cardiovascular disease, particularly ischemic heart disease and congestive heart failure. Similarly, Section 5.1.1 characterizes the available evidence by which inhalation exposure to $PM_{2.5}$ could progress from initial events to endpoints relevant to the respiratory system.

However, the evidence for how the initial events and subsequent endpoints could lead to the observed increases in respiratory ED visits and hospital admissions, for particularly chronic obstructive pulmonary disease (COPD) and asthma, is limited. Collectively, the progression demonstrated in the available evidence for cardiovascular morbidity (and to a lesser extent, respiratory morbidity) supports potential biological pathways by which short-term $PM_{2.5}$ exposures could result in mortality.

11.1.2 Associations between Short-Term $PM_{2.5}$ Exposure and Total (Nonaccidental) Mortality in All-Year Analyses

In previous PM reviews, specifically the 2004 PM AQCD (U.S. EPA, 2004) and the 2009 PM ISA (U.S. EPA, 2009), the number of multicity studies that examined the association between short-term $PM_{2.5}$ exposure and total (nonaccidental) mortality was rather limited with the largest body of evidence encompassing single-city studies. The single-city studies evaluated in previous reviews were conducted in diverse geographic locations and reported primarily consistent positive associations between $PM_{2.5}$ exposure and daily mortality. The limited number of large multicity studies included in those reviews could be attributed to the rather small sample of ambient $PM_{2.5}$ monitoring data available at that time with the majority of monitoring being initiated in the years 1999 and 2000. Recent multicity studies encompass a larger number of years and sometimes include daily $PM_{2.5}$ concentrations, whereas previous studies were often limited to a shorter time series and $PM_{2.5}$ data that was only collected every 3rd or 6th day.

Recent multicity studies conducted across the U.S., Canada, Europe, and Asia, as well as meta-analyses (Adar et al., 2014; Atkinson et al., 2014) that examined a larger number of studies of short-term $PM_{2.5}$ exposures and mortality, primarily report consistent positive associations within the range of risk estimates reported in the 2009 PM ISA (i.e., 0.19% (Lippmann et al., 2013a) to 2.80% (Kloog et al., 2013)) (Figure 11-1). An exception to this trend across multicity studies is Lanzinger et al. (2016), which as part of the "ultrafine particles—an evidence based contribution to the development of regional and European environmental and health policy" or UFIREG study observed no evidence of an association between short-term $PM_{2.5}$ exposure and total (nonaccidental) mortality. The results of the UFIREG study may be a reflection of the short time series for each city included in the study (i.e., approximately 2 years), compared to the other multicity studies that consisted of longer study durations as summarized in Table 11-1. Additionally, in contrast to Ostro et al. (2006), a recent study by Young et al. (2017) did not provide any evidence of an association between short-term $PM_{2.5}$ exposure and mortality when examining eight air basins in California. The difference in results between these two studies could be attributed to: (1) the larger spatial domain over which exposure was assigned in Young et al. (2017), i.e., an air basin (encompassing multiple counties), compared to Ostro et al. (2006), i.e., a single county; (2) the use of only the highest monitor on each day to assign exposure Young et al. (2017) versus the averaging of all monitors over the spatial domain examined Ostro et al. (2006); and (3) the statistical models used in both studies.



NMMAPS = National Morbidity, Mortality, and Air Pollution Study; UFIREG = Ultrafine Particles—an evidence based contribution to the development of regional and European environmental and health policy.

[a]Results are from modeled $PM_{2.5}$ analysis, analysis focusing on measured $PM_{2.5}$ reported 1.21% (95% CI: 0.94, 1.47).

[b]Only four of the five cities measured $PM_{2.5}$.

[c]Shi et al. (2015) and Zanobetti et al. (2014b) only had data for all-cause mortality including accidental mortalities.

[d]Main model used in Young et al. (2017) included current and average of 3 previous days daily maximum temperature, daily minimum temperature, and maximum daily relative humidity.

[e]Sensitivity analysis in Young et al. (2017) focusing on only the San Fransisco Bay air basin, dropping out the maximum daily relative humidity term, where the shortest duration of lag days examined was 0−3 days.

[f]Ueda et al. (2009) presented results for three different modeling approaches, which are presented here: GAM, GLM, and case-crossover.

[g]Atkinson et al. (2014) primarily focused on single-day lag results.

[h]Adar et al. (2014) focused on single-day lag results, specifically lag 0, 1, or 2.

Note: †Studies published since the 2009 PM ISA. Black circles = U.S. and Canadian multicity studies evaluated in the 2004 PM AQCD and 2009 PM ISA. Red circles = Multicity studies and meta-analyses published since the completion of the 2009 PM ISA. Corresponding quantitative results are reported in the Supplemental Material for this chapter, see (U.S. EPA, 2018a).

Figure 11-1 Summary of associations between short-term $PM_{2.5}$ exposure and total (nonaccidental) mortality in multicity studies for a 10 μg/m^3 increase in 24-hour average concentrations.

11.1.2.1 Examination of $PM_{2.5}$-Mortality Relationship through Causal Modeling Statistical Approaches

In addition to traditional epidemiologic study designs (e.g., time-series, case-crossover), there has been a growing interest in applying causal modeling statistical approaches to examine the $PM_{2.5}$-mortality relationship. Within the studies that examined short-term $PM_{2.5}$ exposure and mortality, two types of

causal modeling approaches have been employed: (1) causal inference (Schwartz et al., 2017; Schwartz et al., 2015) and (2) quasi-experimental (Yorifuji et al., 2016) (Table 11-2).

Table 11-2 Methods and results from epidemiologic studies that applied causal inference statistical approaches.

Study	Method	Results
Causal inference		
†Schwartz et al. (2015) Boston, MA (2004–2009)	Instrumental variable: used back trajectories of $PM_{2.5}$ along with variables for wind speed and sea level pressure in a 2-stage approach to develop temperature independent predictions of daily $PM_{2.5}$ concentrations (the instrument). Analyses used 2-day mean instrument concentrations.	0.53% (95% CI: 0.09, 0.97) for a 1 μg/m^3 increase in the instrument for $PM_{2.5}$
	Propensity score: modeled $PM_{2.5}$ in a linear regression with variables for time, temperature, day of week, and copollutants (O_3, NO_2, SO_2, and CO). The predicted $PM_{2.5}$ concentrations from the model represent the propensity score. After trimming days with highest and lowest 5% propensity scores, divided the scores into deciles. Analyses used 2-day mean predicted $PM_{2.5}$ concentrations.	0.50% (95% CI: 0.2, 0.8) for a 1 μg/m^3 increase in $PM_{2.5}$
	Sensitivity analysis: using an approach similar to Granger causality, the instrumental variable was used to examine the association between the instrument 2 days after the day of death on today's value of daily deaths.	Failed to reject null hypothesis, (P = 0.93; 95% CI: −0.43, 0.47)
†Schwartz et al. (2017) Boston, MA (2000–2009)	Instrumental variable: planetary boundary layer (PBL) and wind speed at lag 0 and lag 1 were regressed on $PM_{2.5}$, BC or NO_2 concentrations to generate a single instrumental variable for each pollutant representative of local pollution, taking into consideration variation within month-by-year strata and within deciles of temperature. Analyses used 2-day mean instrument concentrations.	0.90% (95% CI: 0.25, 1.56) for an IQR increase in the instrument for local $PM_{2.5}$
	Sensitivity analysis: using an approach similar to Granger causality, the instrumental variable was used to examine the association between the instrument 2 and 3 days after the day of death on today's value of daily deaths.	0.18% (95% CI: −0.45, 0.81) for an IQR increase in the instrument for local $PM_{2.5}$

Table 11-2 (Continued): Methods and results from epidemiologic studies that applied causal inference statistical approaches.

Study	Method	Results
Quasi-experimental		
†Yorifuji et al. (2016) Tokyo, Japan (2000–2012)	Compared mortality rates in Tokyo, Japan, which had a strict diesel emissions control ordinance in place and Osaka, Japan, which did not. Interrupted time-series analysis used to regress log of age-standardized mortality rates in Tokyo, weighted by daily trends in Osaka, on the $PM_{2.5}$ concentrations and estimated rate ratios across 3-year intervals using the three years prior to the ordinance as a reference period.	Difference in mortality between 2000–2003 and 2009–2012: Total: −6.0% Cardiovascular: −11.0% IHD: −10.0% Cerebrovascular: −6.2% Pulmonary: −22.0%

BC = black carbon, IHD = ischemic heart disease.

†Studies published since the 2009 PM ISA.

Through causal inference statistical approaches, the goal is to "estimate the difference (or ratio) in the expected value of [an] outcome in the population under the exposure they received versus what it would have been had they received an alternative exposure" (Schwartz et al., 2015). Schwartz et al. (2015) and Schwartz et al. (2017) examined instrumental variable and propensity score approaches using data from Boston, MA. Through the instrumental variable approach, a variable is constructed that is only related to the outcome through the exposure of interest, while the propensity score approach represents the conditional probability of exposure assignment given a vector of observed covariates (Schwartz et al., 2015).

Schwartz et al. (2015) and Schwartz et al. (2017) took different approaches to constructing instrumental variables, and both reported evidence of an association between the $PM_{2.5}$ instrument and mortality (Table 11-2). In Schwartz et al. (2017) this association was found to persist when limiting the analysis to days with 24-hour average $PM_{2.5}$ concentrations <30 $\mu g/m^3$ (0.84% [95% CI: 0.19, 1.50]). Schwartz et al. (2015) and Schwartz et al. (2017) also conducted Granger-like causality tests to examine whether there was evidence of an association between mortality and $PM_{2.5}$ concentrations after the day of death, which would support the possibility that unmeasured confounders were not accounted for in the statistical model. Both Schwartz et al. (2015) and Schwartz et al. (2017) reported no evidence of an association with $PM_{2.5}$ concentrations measured after death.

While Schwartz et al. (2015) and Schwartz et al. (2017) focused on causal inference approaches that result in the development of alternative exposure variables, Yorifuji et al. (2016) conducted a quasi-experimental study that examined whether a specific regulatory action in Tokyo, Japan (i.e., a diesel emission control ordinance) resulted in a subsequent reduction in daily mortality (Table 11-2). The quasi-experimental design relies on some intervention that is meant to reduce ambient air pollution

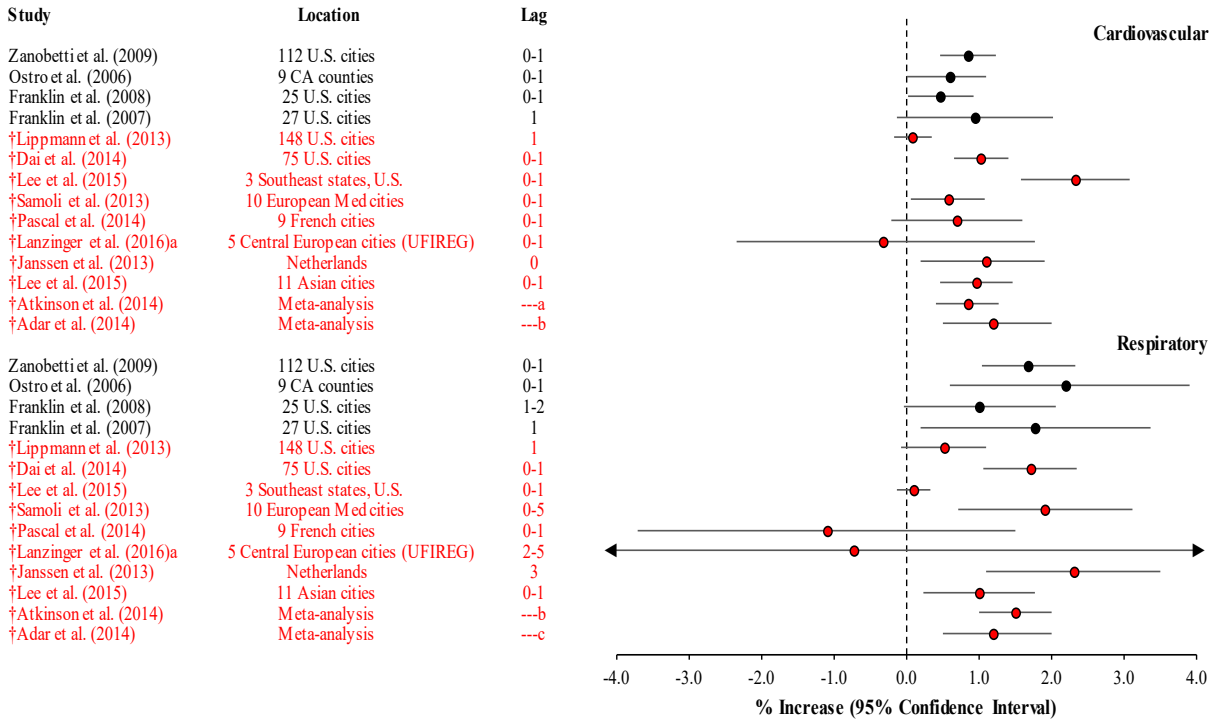
concentrations. Yorifuji et al. (2016) reported evidence of a reduction in mortality in Tokyo due to the ordinance, in comparison to Osaka, Japan, which did not have a similar diesel emission control ordinance in place.

Although the studies to date that have used causal modeling statistical approaches are limited to two locations, overall the studies provide additional support for the relationship between short-term $PM_{2.5}$ exposure and mortality described in previous and recent studies, including those highlighted in Figure 11-1. Additionally, the study by Yorifuji et al. (2016) demonstrates that improvements in air quality, including reductions in $PM_{2.5}$ concentrations, contribute to public health benefits such as reductions in daily mortality.

11.1.3 Associations between Short-Term $PM_{2.5}$ and Cause-Specific Mortality in All-Year Analyses

Single and multicity studies evaluated in the 2009 PM ISA that examined cause-specific mortality reported consistent positive associations with both cardiovascular and respiratory mortality. The magnitude of the association was larger for respiratory mortality, but also had greater confidence intervals due to the smaller number of respiratory-related deaths compared to cardiovascular-related deaths.

Recent multicity studies have further examined the relationship between short-term $PM_{2.5}$ exposure and cause-specific mortality, with some studies conducting additional examinations of specific cardiovascular or respiratory deaths (e.g., stroke, COPD as mentioned in Section 5.1.9 and Section 6.1.9). These studies generally report positive associations, which is consistent with the studies evaluated in the 2009 PM ISA. Overall, these studies report larger risk estimates for respiratory mortality, but many of the confidence intervals are larger than those for cardiovascular mortality due to cardiovascular mortality representing a greater percentage of total mortality (~35%) compared to respiratory mortality (<10%) (American Heart Association, 2011) (Figure 11-2). A more thorough discussion of cardiovascular- and respiratory-related mortality can be found in the respective cardiovascular and respiratory effects sections (Section 5.1.9 and Section 6.1.9).



UFIREG = Ultrafine Particles—an evidence-based contribution to the development of regional and European environmental and health policy.

[a]Only four of the five cities measured $PM_{2.5}$.

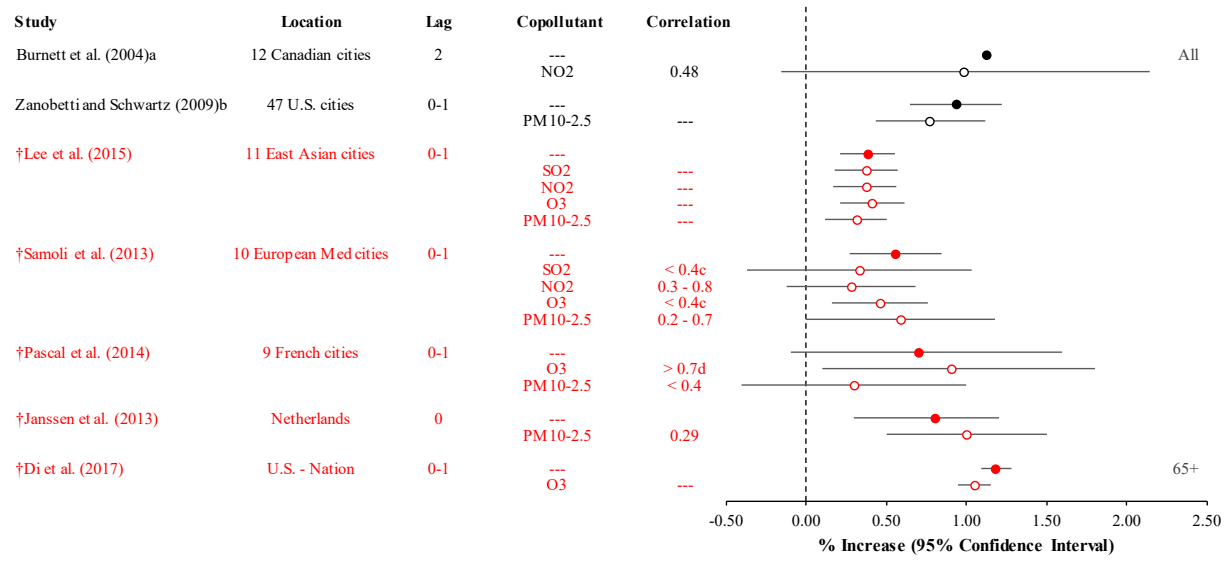
11.1.4 Potential Copollutant Confounding of the $PM_{2.5}$-Mortality Relationship

Analyses of potential copollutant confounding of the $PM_{2.5}$-mortality relationship in the 2009 PM ISA indicated that associations remain robust, and relatively unchanged in copollutant models. These conclusions were based primarily on a multicity study conducted in Canada (Burnett et al., 2004) along with single-city studies reviewed in the 2004 PM AQCD (U.S. EPA, 2004), and supporting evidence from studies that examined the PM_{10}-mortality relationship. Recent multicity studies that assess the potential for copollutant confounding of the $PM_{2.5}$-mortality relationship are limited to Europe and Asia. However, similar to the 2004 PM AQCD and 2009 PM ISA, analyses of potential confounding by gaseous pollutants (i.e., SO_2, NO_2, and O_3) were limited in number, with additional analyses focusing on copollutant models with $PM_{10-2.5}$. Overall, studies that examined potential copollutant confounding reported that $PM_{2.5}$-mortality risk estimates remained positive and relatively unchanged in models with both gaseous pollutants and $PM_{10-2.5}$, although confidence intervals increased in some cases. Across studies that examined potential confounding by gaseous copollutants (Di et al., 2017a; Lee et al., 2015a; Pascal et al., 2014; Samoli et al., 2013), the $PM_{2.5}$-mortality relationship was relatively unchanged (Figure 11-3). Those studies that present correlation coefficients provide additional information to support the results from the copollutant analyses due to the low ($r < 0.4$) to moderate correlations ($r = 0.4 < 0.7$) observed.

When assessing the evidence across the studies that examined potential copollutant confounding by $PM_{10-2.5}$, the approaches used to estimate $PM_{10-2.5}$ varied across studies, which could contribute to exposure measurement error and complicate the overall interpretation of results (Section 3.3.1.1). However, regardless of the method used to estimate $PM_{10-2.5}$ concentrations, in copollutant models the $PM_{2.5}$-mortality association was relatively unchanged, but in some cases confidence intervals were larger compared to the single pollutant models (Figure 11-3). The results from multicity studies that examined potential confounding of the $PM_{2.5}$-mortality relationship by $PM_{10-2.5}$ are further supported by a meta-analysis conducted by Adar et al. (2014). The authors focused almost exclusively on the $PM_{10-2.5}$-mortality relationship, but also examined $PM_{2.5}$. In copollutant analyses the authors observed that $PM_{2.5}$-mortality associations were relatively unchanged when including $PM_{10-2.5}$ in the model (quantitative results not presented).



[a]Data from 1998−2000 when PM measured by TEOM. Standard error for the single-pollutant $PM_{2.5}$ result was not reported in the study so only the central estimate is included.

[b]Analysis focused on 112 U.S. cities, but $PM_{10-2.5}$ only measured in 47 U.S. cities.

Note: †Studies published since the 2009 PM ISA. Closed circles = single-pollutant results. Open circles = copollutant results. Corresponding quantitative results are reported in the Supplemental Material for this chapter. See (U.S. EPA, 2018a).

Figure 11-3 Summary of association between short-term $PM_{2.5}$ exposure and total (nonaccidental) mortality for a 10 μg/m^3 increase in 24-hour average concentrations in single- and copollutant models from previous and recent multicity studies.

11.1.5 Other Potential Confounders of the $PM_{2.5}$-Mortality Relationship

11.1.5.1 Long-Term Temporal Trends and Weather

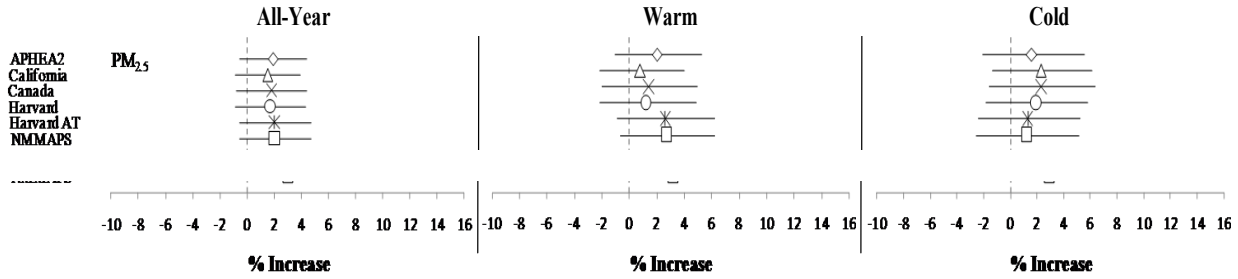
In the 2009 PM ISA, studies that examined the influence of alternative model specification, in terms of controlling for temporal trends or the confounding effects of weather were limited to studies of PM_{10}. Of these studies Welty and Zeger (2005) conducted the most systematic evaluation and found that PM_{10}-mortality risk estimates remained robust across various combinations of degrees of freedom (df) to control for temporal trends and weather covariates. At the completion of the 2009 PM ISA, there were not studies of short-term $PM_{2.5}$ exposure and mortality that conducted similar analyses to address whether the results observed in PM_{10} studies were consistent for $PM_{2.5}$. Recent multicity, as well as a few single-city, studies specifically examined the influence of model specification on the $PM_{2.5}$-mortality association

while others conducted sensitivity analyses to examine whether the primary statistical model was appropriate.

Ueda et al. (2009) in a study of 20 Japanese cities and Sacks et al. (2012) in a study in Philadelphia, PA conducted systematic evaluations of alternative models to adjust for long-term temporal trends and weather covariates. Ueda et al. (2009) examined a generalized additive model (GAM), generalized linear model (GLM), and logistic regression through a case-crossover analysis to examine the relationship between short-term air pollution exposure, including $PM_{2.5}$, and mortality. Across models, the $PM_{2.5}$-mortality association remained relatively unchanged after increasing the df employed (i.e., 3 or 6) to control for the potential nonlinear relationship between ambient temperature and mortality. These results are consistent with Lee et al. (2015c) in a study of three southeastern U.S. states where the $PM_{2.5}$-mortality association remained robust when increasing the df for the temperature covariate from 2 to 4.

In Ueda et al. (2009), the largest influence on the $PM_{2.5}$-mortality association was observed for the GLM when changing the approach to adjust for seasonality from using an indicator variable of every 2 months to the more traditional approach of using a natural spline. The results using the natural spline in the GLM (0.43% [95% CI: 0.00, 0.86]; lag 1) were more consistent with those observed in the GAM (0.53% [95% CI: 0.13, 0.94]; lag 1) where penalized splines were used to adjust for seasonality. It is worth noting that overall the results of the comparisons conducted by Ueda et al. (2009) are consistent with previous analyses that have shown that the GLM, GAM, and case-crossover approach all result in relatively consistent results (Schwartz et al., 2003).

Sacks et al. (2012) took a different approach than Ueda et al. (2009) by examining the influence of model specification using the models employed in recent multicity studies conducted by Burnett and Goldberg (2003), Zanobetti and Schwartz (2009), Zanobetti and Schwartz (2008), Ostro et al. (2008), Samoli et al. (2005), and Dominici et al. (2005) within the context of a similar data set. These models differed by the approach used to control for long-term temporal trends (i.e., number of df per year) and the potential confounding effects of weather (i.e., the weather covariate included in the model, and the accompanying lag and/or df for the covariate). Focusing on daily cardiovascular mortality and daily air pollution concentrations, including $PM_{2.5}$, the authors observed in all-year analyses that results for $PM_{2.5}$ were relatively similar across models with the percent increase in cardiovascular mortality ranging from 1.5–2.0% (Figure 11-4). In seasonal analyses there was more variability in the magnitude of the association across models (i.e., cold Season: 1.2–2.3%; warm Season: 0.8–2.7%), but the direction of the association remained consistent.



Note: APHEA2 = Samoli et al. (2005); California = Ostro et al. (2008); Canada = Burnett and Goldberg (2003); Harvard = Zanobetti and Schwartz (2009); Harvard AT = Zanobetti and Schwartz (2008); and NMMAPS = Dominici et al. (2005).

Figure 11-4 Percent increase in cardiovascular mortality for a 10 μg/m^3 increase in 24-hour average $PM_{2.5}$ concentrations at lag 0−1 in Philadelphia, PA (May 1992−September 1995) across statistical models used in multicity studies.

Whereas Ueda et al. (2009) and Sacks et al. (2012) conducted systematic evaluations on the influence of model specification on the $PM_{2.5}$-mortality relationship, other studies conducted more targeted analyses. Lee et al. (2015a) and Samoli et al. (2013) in 11 East Asian cities and 10 European Mediterranean cities, respectively, both examined the influence of various approaches to control for long-term temporal trends on the $PM_{2.5}$-mortality relationship. In sensitivity analyses where the df employed per year ranged from 6 to 12, Lee et al. (2015a) did not observe any evidence that $PM_{2.5}$-mortality risk estimates changed as the df increased. Samoli et al. (2013) examined alternative approaches to control for long-term temporal trends through either setting the df a priori, using absolute sum of the residuals of the partial autocorrelation function (PACF) or a case-crossover design in the context of a Poisson model with a three-way interaction. Across each approach, the authors observed that the magnitude of the association was smallest when specifying the df per year to use a priori, but a positive association persisted across all approaches ranging from 0.55 to 0.97%.

In the Denver Aerosol Sources and Health (DASH) study, Kim et al. (2015) further confirmed the results from previous studies that examined alternative specifications to account for long-term temporal trends and the confounding effects of weather. The authors examined both decreasing and increasing the df to control for long-term temporal trends, matching the lags of meteorological covariates to those of the pollutants, and a squared term and moving averages of extended days (i.e., lags 0, 1−3, and 4−7) for temperature. Across all of these alternative model specifications, Kim et al. (2015) found that results were relatively consistent with the main statistical model (2.63% [95% CI: −0.22, 5.44]; lag 0−3 days unconstrained DL). Compared to Kim et al. (2015), Lee et al. (2015c) in a study of three southeastern

U.S. states and Di et al. (2017a) a national analysis only examined the sensitivity of the $PM_{2.5}$-mortality relationship to changing the df for weather covariates. Lee et al. (2015c) observed that increasing the df from 2 to 4 for the same-day temperature covariate resulted in relatively consistent risk estimates, with the percent increase in mortality ranging from 1.57 to 1.63% at lag 0−1 days. The results of Lee et al. (2015c) are consistent with those reported in Di et al. (2017a) where it was observed that increasing the natural spline df to 6 and 9 for both the temperature and dew point temperature covariates did not change the magnitude of the $PM_{2.5}$-mortality association when compared to the main analysis that used 3 df.

The recent studies focusing on short-term $PM_{2.5}$ exposures and mortality that examined alternative approaches to controlling for long-term temporal trends and the confounding effects of weather in all-year analyses are consistent with the observations from studies focusing on PM_{10} in the 2009 PM ISA. The limited assessment of model specification when conducting seasonal analyses provides some evidence that associations may be more sensitive to model specification. Overall, the results from these studies indicate that alternative approaches may influence the magnitude of the $PM_{2.5}$-mortality association, but have not been found to influence the direction of the observed association.

11.1.5.2 Influence of Long-Term $PM_{2.5}$ Concentrations on Short-Term $PM_{2.5}$ Associations

It has often been questioned whether the associations observed in epidemiologic studies of short-term air pollution exposure reflect the impact of the short-term exposure on health or are partly a reflection of exposure to air pollution over many years. This question is often posed for $PM_{2.5}$, where a large body of epidemiologic evidence demonstrates strong associations between both short- and long-term $PM_{2.5}$ exposure and mortality. In a study of the New England area, Shi et al. (2015) attempted to address the impact of different exposure durations on the $PM_{2.5}$-mortality relationship by examining both long- and short-term $PM_{2.5}$ exposures and mortality in the same statistical model. The authors observed in analyses using the full cohort that the association between short-term $PM_{2.5}$ exposure and mortality was relatively unchanged in models without adjustment (2.14% [95% CI: 1.38, 2.89]; lag 0−1) and with adjustment (2.08 [95% CI: 1.32, 2.84]) for long-term $PM_{2.5}$ exposures. These results provide additional evidence confirming the relationship between short-term $PM_{2.5}$ exposure and mortality.

11.1.6 Effect Modification of the $PM_{2.5}$-Mortality Relationship

The examination of effect modification of the $PM_{2.5}$-mortality relationship can be divided into several categories. There are some studies that examine whether specific individual- or population-level characteristics modify the $PM_{2.5}$-mortality association, which can provide information pertaining to whether certain populations are at increased risk of a PM-related health effect. Other studies focus more

broadly on examining those factors that potentially modify that $PM_{2.5}$-mortality association, and may explain some of the observed geographic heterogeneity in risk estimates. A detailed discussion of populations potentially at increased risk of PM-related health effects can be found in Chapter 12. As a result, this subsection focuses on exploring those factors that may modify the $PM_{2.5}$-mortality association and provide insight on the heterogeneity in risk estimates.

11.1.6.1 Season

The examination of whether $PM_{2.5}$-mortality associations differ by season can provide a better understanding of the overall relationship between short-term $PM_{2.5}$ exposure and mortality. The 2009 PM ISA reported some evidence that $PM_{2.5}$-mortality associations are larger in magnitude during the warm season, specifically the spring, with the majority of this evidence coming from U.S. multicity studies (Zanobetti and Schwartz, 2009; Franklin et al., 2008). Recent multicity studies generally support the seasonal patterns of associations previously observed, and due to the larger sample size allow for a more robust evaluation of potential seasonal differences.

Among the recent U.S.-based multicity studies, Dai et al. (2014) observed a larger risk during the spring with a 2.9% (95% CI: 2.2, 3.5%) increase in total (nonaccidental) mortality at lag 0−1, but positive associations were observed across the summer, fall, and winter ranging from 0.46−1.2%. Although the magnitude of the association was larger in Dai et al. (2014), in the NPACT study, Lippmann et al. (2013a) observed a larger $PM_{2.5}$-mortality effect in the warm season (April–September) (0.35% [95% CI: 0.13, 0.58%]; lag 0) and evidence of no association in the cold season among 148 U.S. cities. Interestingly, Krall et al. (2013) observed no evidence of seasonal differences in $PM_{2.5}$-mortality associations across 72 U.S. cities, which included the same study years as Dai et al. (2014) and Lippmann et al. (2013a). Although some study design aspects differ among the studies, the overall design of Krall et al. (2013) and Lippmann et al. (2013a) are similar as are the underlying statistical models, which further complicates the interpretation of the disparate results with respect to seasonal associations between the studies. However, each of the studies reported positive associations in all-year analyses even though the magnitude varied (Figure 11-1).

European multicity studies support the results observed in Dai et al. (2014) and Lippmann et al. (2013a) of associations larger in magnitude during warmer months of the year. In a study of 20 European Mediterranean cities, Samoli et al. (2013) observed larger associations during the warm season (2.2% [95% CI: 1.5, 3.0]; lag 0−1) compared to the cold season (0.23% [95% CI: −0.08, 0.54]). Pascal et al. (2014) also observed larger associations during the summer (3.4% [95% CI: 1.8, 5.1]; lag 0−1) compared to the other three seasons with estimates ranging from −0.6 to 0.9%. However, in copollutant models with O_3 the authors observed that associations across all seasons persisted, except the summer (0.50% [95% CI: −3.3, 4.4]) indicating some evidence of potential confounding by O_3.

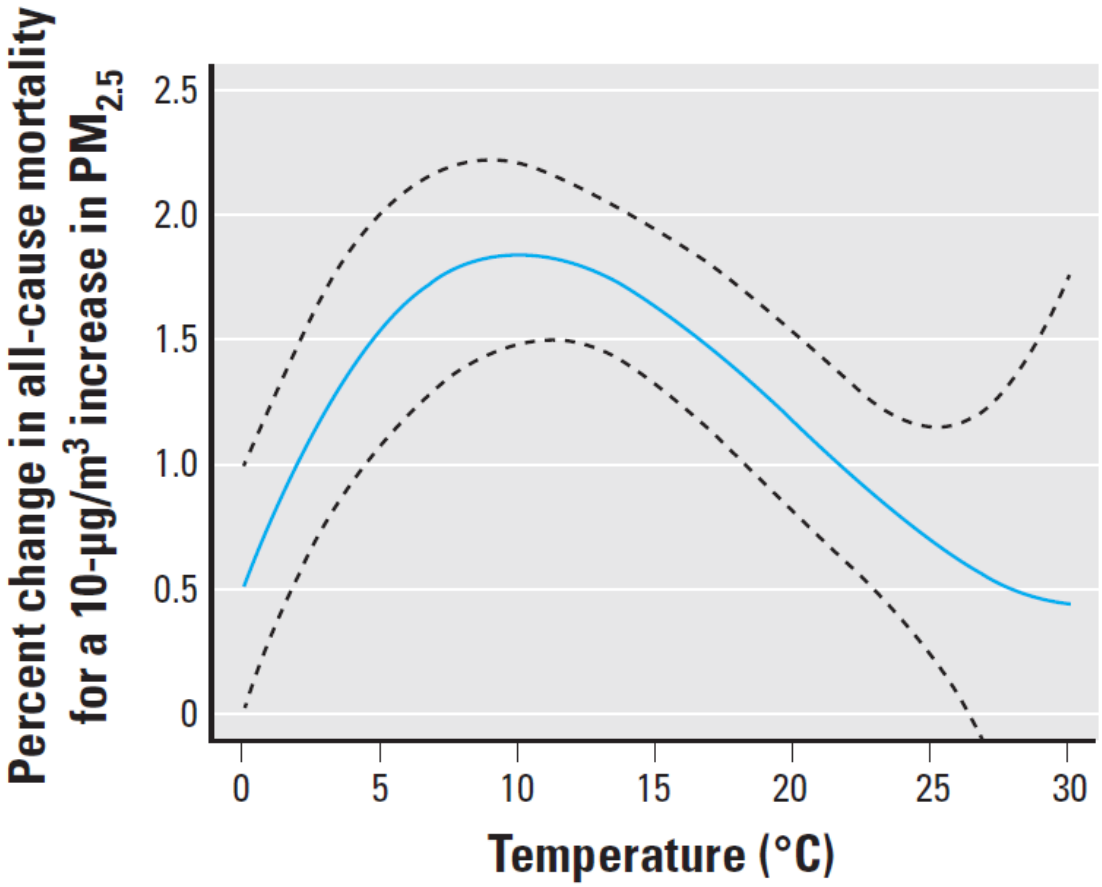
Across recent multicity studies, there was general agreement that $PM_{2.5}$-mortality associations were larger in magnitude during warmer months. However, it remains unclear if copollutants confound the seasonal patterns in associations observed. Across most studies the pattern of seasonal associations persisted using different methods to examine whether there was evidence of seasonal differences in associations with some studies relying on stratified analyses (Dai et al., 2014; Samoli et al., 2013) and others incorporating interaction terms between $PM_{2.5}$ and season (Pascal et al., 2014; Lippmann et al., 2013a).

11.1.6.2 Temperature

Seasonal analyses, such as those discussed above, indirectly take into consideration the role of temperature on the $PM_{2.5}$-mortality association. However, these studies do not directly address the question of whether higher or lower temperature days modify the $PM_{2.5}$-mortality association. Studies by Dai et al. (2014) and Pascal et al. (2014) further explore the role of temperature on the $PM_{2.5}$-mortality relationship.

Previous studies have demonstrated an inverted U-shape curve between temperature and indoor ventilation, which potentially influences exposure to $PM_{2.5}$ (Koutrakis et al., 2005). In a study of 75 U.S. cities, Dai et al. (2014) examined the influence of city-season mean temperature on the $PM_{2.5}$-mortality association. Consistent with the observations of Koutrakis et al. (2005) the authors found a smaller $PM_{2.5}$-mortality association during high and low temperatures, which could be attributed to reduced indoor penetration of $PM_{2.5}$ as a result of less ventilation (Figure 11-5).

Whereas Dai et al. (2014) focused on examining the $PM_{2.5}$-mortality relationship across the distribution of city-season temperatures, Pascal et al. (2014) focused on the "extra effect of PM during warm days." The authors defined warm days as those days "when the mean temperature equals or exceeds the 97.5th percentile of the mean temperature distribution" (Pascal et al., 2014). Stratifying on days above the 97.5th percentile, Pascal et al. (2014) reported a larger increase in nonaccidental mortality on warm days (1.4% [95% CI: −5.5, 8.9]; lag 0−1) compared to nonwarm days (0.70% [95% CI: −0.10, 1.5]); however, confidence intervals were large indicating a small number of days with temperatures within this range of the temperature distribution. The interaction term examining the additional PM-mortality effect attributed to high temperatures was similar to the warm days stratified result, i.e., indicating potential evidence of effect measure modification, but with wide confidence intervals (interaction ratio: 1.03 [95% CI: 0.97, 1.11]).



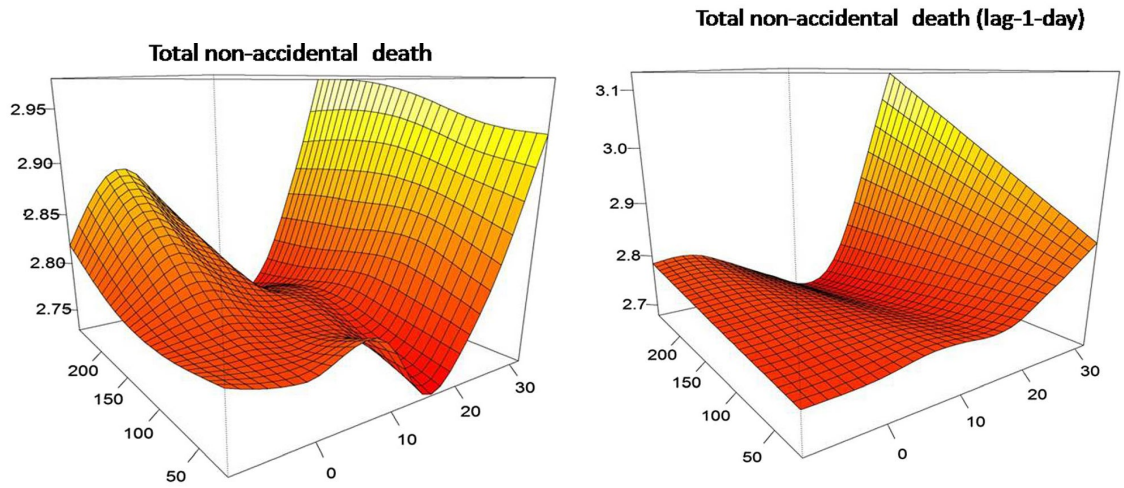
Source: Permission pending, Dai et al. (2014).

Figure 11-5 Relationship between estimated $PM_{2.5}$-mortality association and temperature.

Additional studies conducted by Sun et al. (2015) and Li et al. (2015), in Hong Kong and Beijing, respectively, had mean $PM_{2.5}$ concentrations over 20 µg/m^3 during the study duration, but used unique approaches to examine the potential interactive effect of temperature on the $PM_{2.5}$-mortality relationship. Sun et al. (2015) first identified the lag structure over which there was evidence of a temperature-mortality relationship for both cold and warm temperatures using generalized cross-validation (GCV). This process identified a 0−6-day lag for cold temperatures and a 0−1-day lag for warm temperatures. The authors then defined the cold and warm temperature cutoff by identifying the temperature at which the log relative risk of the temperature-mortality relationship was equal to zero resulting in low temperatures being defined as <22°C, medium temperatures as 22–25°C, and high temperatures as ≥25° C. In a stratified analysis, Sun et al. (2015) reported evidence of a larger association for $PM_{2.5}$ and total (nonaccidental) mortality in Hong Kong for lower temperatures (0.94% [95% CI: 0.65,

1.2]; lag 0−1) when compared to higher temperatures (0.47% [95% CI: 0.18, 0.76]). This pattern of associations persisted in copollutant models with NO_2, SO_2, and O_3.

A different pattern of $PM_{2.5}$-mortality associations was observed by Li et al. (2015) when examining the influence of temperature. The authors first visually examined the combined effects of temperature and $PM_{2.5}$ on mortality using a nonparametric bivariate response surface. Using the results of the bivariate model allowed for the identification of temperature ranges that could be examined by conducting a stratification analysis (i.e., low temperature <2.6ºC, medium temperature 2.6–23.5ºC, and high temperature >23.5ºC). Whereas Sun et al. (2015) observed larger mortality associations only at higher temperatures, in the bivariate response model Li et al. (2015) reported evidence of larger $PM_{2.5}$-mortality associations at both low and high temperatures, specifically at lag 0 (Figure 11-6). However, it is important to note that the definition of low temperature for Li et al. (2015) and Sun et al. (2015) differed, complicating the comparison of results between these two studies.



Note: *y*-axis = percent increase in mortality, *z*-axis = $PM_{2.5}$ concentrations, and *x*-axis = temperature (°C).
Source: Permission pending, Li et al. (2015).

Figure 11-6 Bivariate $PM_{2.5}$-temperature response surfaces for total (nonaccidental) mortality using same-day 24-hour mean temperature and lag 0 and lag 1 $PM_{2.5}$ concentrations.

The observation from the bivariate model was confirmed when examining $PM_{2.5}$-mortality associations at the various temperature ranges in the stratified analysis. The magnitude of the association was similar at both the low and high temperatures at both lag 0 (low temperature: 1.3 [95% CI: 0.46, 2.0]; high temperature: 1.4 [95% CI: 0.35, 2.4]) and lag 1 (low temperature: 1.1 [95% CI: 0.48, 1.7]; high temperature: 1.1 [95% CI: 0.76, 2.1]).

Overall, the examination of the potential modification of the $PM_{2.5}$-mortality relationship by temperature remains unclear. Although there is some evidence of an increase in the magnitude of the $PM_{2.5}$ association at both lower and higher temperatures in studies conducted at higher $PM_{2.5}$ concentrations, to date studies conducted within the U.S. have not provided evidence of a modification of the $PM_{2.5}$-mortality association by temperature.

11.1.6.3 City and Regional Characteristics

It has often been hypothesized the heterogeneity in $PM_{2.5}$-mortality associations observed across cities could be attributed to city-specific differences in population demographics, $PM_{2.5}$ composition, or exposure characteristics. Studies of population demographics often focus on whether there is evidence of effect modification and not on how risk may change between cities due to demographic differences. In the 2009 PM ISA, the evaluation of the observed heterogeneity in $PM_{2.5}$-mortality associations was limited to studies examining whether individual $PM_{2.5}$ components or the prevalence of air conditioning use, a surrogate for decreased PM penetration indoors, modified the association. Although examining the modification of the PM-mortality relationship by $PM_{2.5}$ components included studies focusing on PM_{10}, overall a number of components were found to potentially explain the city-to-city heterogeneity (U.S. EPA, 2009). Additionally, there was some evidence that the prevalence of air conditioning (AC) use across cities modifies the $PM_{2.5}$-mortality association and that $PM_{2.5}$-mortality associations vary by region of the country (i.e., east vs. west) (U.S. EPA, 2009). Although $PM_{2.5}$ composition, AC use, and geographic location may explain some of the heterogeneity in $PM_{2.5}$-mortality risk estimates, at the completion of the 2009 PM ISA it remained unclear what factors or combination of factors explain the observed heterogeneity. Recent studies discussed in the following sections have expanded upon the initial analyses detailed in the 2009 PM ISA by examining whether specific $PM_{2.5}$ components/mixtures or exposure characteristics provide information that explains the heterogeneity in $PM_{2.5}$-mortality associations observed in multicity studies.

11.1.6.3.1 Composition/Mixtures

The examination of effect modification of the $PM_{2.5}$-mortality association, by either an individual $PM_{2.5}$ component or the proportion of a $PM_{2.5}$ component to mass, is one of the traditional approaches that has been employed to examine the influence of PM composition on the $PM_{2.5}$-mortality relationship. Although detailed as one of the main approaches used to examine the association between a $PM_{2.5}$ component and a health outcome in Mostofsky et al. (2012), these studies are discussed within this section because they have primarily been used as a means to explain the heterogeneity in $PM_{2.5}$-mortality risk estimates observed between cities or regions of a country. Other studies focusing specifically on examining the effect of individual $PM_{2.5}$ components on mortality are detailed in Section 11.1.11.

As part of the NPACT study and in a study of 75 U.S. cities, Lippmann et al. (2013a) and Dai et al. (2014) conducted analyses similar to those in Franklin et al. (2008), which was evaluated in the 2009 PM ISA, to examine whether specific pollutants modify the $PM_{2.5}$-mortality relationship. Lippmann et al. (2013a) examined the modifying effect of long-term average pollutant concentrations, while Dai et al. (2014) and Franklin et al. (2008) examined the $PM_{2.5}$ component to $PM_{2.5}$ mass proportion. In a second-stage analysis, Lippmann et al. (2013a) reported evidence that as the IQR of mean concentrations of pollutants increased across cities, the $PM_{2.5}$-mortality association increased in magnitude, specifically with SO_4^{2-}, weekday excess $PM_{2.5}$, Pb, and V. There was additional evidence that other pollutants (e.g., Cu, Se) may also contribute to modifying the $PM_{2.5}$-mortality association, but to a lesser extent, as was evident by the wider confidence intervals. Dai et al. (2014) used the monthly component-to-$PM_{2.5}$ proportion in the second-stage analysis to examine effect modification and observed as the distribution of the proportion increased from the 10th to 90th percentile there was evidence of larger $PM_{2.5}$-mortality associations for Si, S, and Ca. Although Dai et al. (2014) and Lippmann et al. (2013a) did not report consistent results, Lippmann et al. (2013a) and Franklin et al. (2008) both reported some evidence that SO_4^{2-} potentially increases the magnitude of the $PM_{2.5}$-mortality relationship and may explain some of the heterogeneity in risk estimates.

In addition to the traditional effect modification approaches to examining heterogeneity, such as those used in Lippmann et al. (2013a) and Dai et al. (2014), a number of recent studies have explored alternative, and to an extent more novel approaches such as whether cities have unique pollution profiles, to examine if city or region specific pollutant characteristics help explain differences in $PM_{2.5}$-mortality risk estimates observed between cities and regions within the U.S. One such approach developed by Zanobetti et al. (2014a) explores whether distinct daily pollution profiles modify the $PM_{2.5}$-mortality relationship, and although limited to Boston, MA, could be applicable to examining heterogeneity between cities or regions. The authors used $PM_{2.5}$ component data along with gaseous pollutant data from 1999−2009 to identify five distinct pollution profiles through the use of *k*-means clustering, which was detailed in Austin et al. (2012). The five clusters identified were representative of days with low particles—high O_3; crustal; winter—primary; regional summer; and winter—low primary, higher O_3. In single-pollutant models with $PM_{2.5}$, the authors observed a 1.1% increase in mortality (95% CI: 0.0, 2.2) at lag 0 and a 2.3 % increase (95% CI: 0.9, 3.7) at lag 0−1. When examining whether days with specific pollution profiles modified the $PM_{2.5}$-mortality relationship, Zanobetti et al. (2014a) reported evidence that at lag 0 the winter—primary cluster, which has a strong contribution from traffic and oil combustion, had the largest effect, with some evidence that the crustal and regional summer clusters modified the association. A similar pattern of results was observed when examining lag 0−1, but with the magnitude of the association slightly larger for each pollution profile (Figure 11-7). Overall, this study indicates that specific pollution profiles may modify the $PM_{2.5}$-mortality relationship.

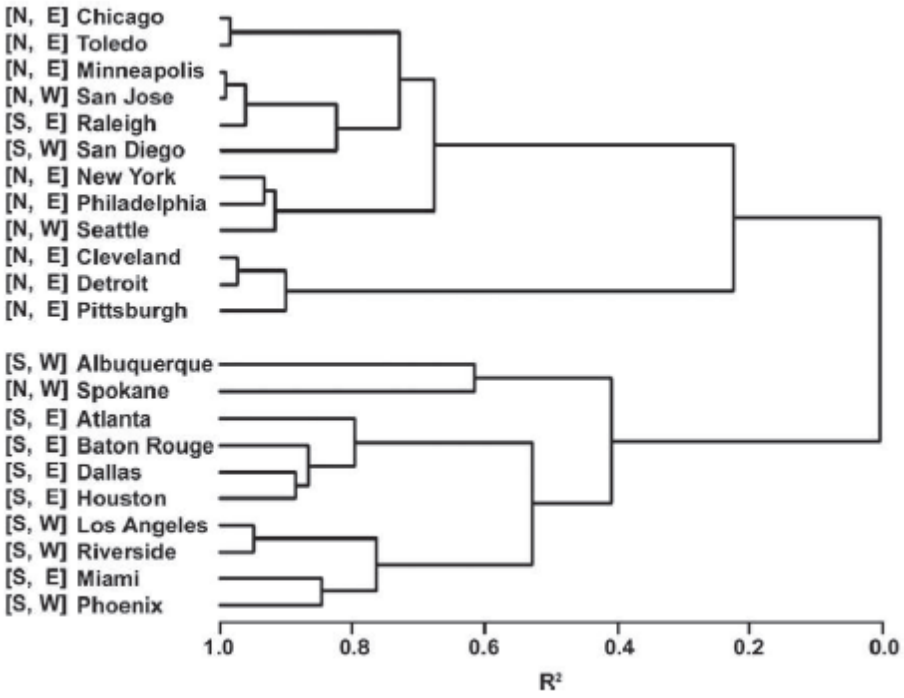
Figure 11-7 Percent increase in mortality for a 10 μg/m^3 increase in $PM_{2.5}$ concentrations at lag 0 and lag 0−1 in single-pollutant models and models containing indicator variables representative of days with specific pollution profiles.

Davis et al. (2011) approached the question of heterogeneity in $PM_{2.5}$-mortality risk estimates using a more qualitative approach. Specifically, the authors focused on whether there was evidence of broad regional patterns in $PM_{2.5}$ component concentrations by examining if groups of cities have similar $PM_{2.5}$ component profiles and if there are regional differences in individual $PM_{2.5}$ component concentrations. To conduct this analysis the authors focused on the 30 cities within the National Morbidity, Mortality, and Air Pollution Study (NMMAPS) that represented the 20 most populated cities and 10 midsize cities that were selected to provide regional coverage across the U.S. Data for 20 $PM_{2.5}$ components from the CSN for the years 2005−2007. Of the cities included in the study, only 17 large and 5 midsize cities had sufficient monitoring data to be included in the cluster analysis. After normalizing the data across cities by calculating the coefficient of divergence (COD) between data sets in each city, a hierarchical cluster analysis was used to group cities with similarities in $PM_{2.5}$ component concentrations. Based on the clustering analysis there was evidence of a north-south delineation in cities with similar $PM_{2.5}$ component concentrations, with the exception of three cities (i.e., Raleigh, San Diego, and Spokane), and not the east-west delineation that has often been observed when examining geographic differences in $PM_{2.5}$-mortality risk estimates as detailed in the 2009 PM ISA (U.S. EPA, 2009) (Figure 11-8). This potential north-south delineation was further reflected when examining whether there are regional differences in individual $PM_{2.5}$ component concentrations using the Wilcoxon two-sample test. In east-west analyses, crustal components (e.g., Al, Si, Ti, Fe, and K) and nitrate were found to be

higher in the West, whereas higher sulfur was observed in the East. There was no evidence of east-west differences in combustion-related components. However, when examining north-south contrasts there was evidence of higher concentrations of combustion-related components, sulfate and nitrate in the North and crustal components and OC in the South. Collectively these results support regional differences in the composition of $PM_{2.5}$. However, within geographic regions there is city-to-city heterogeneity in $PM_{2.5}$ mortality risk estimates, which complicates the interpretation of the regional pattern of associations observed in studies such as Davis et al. (2011).



Note: N = north, S = south, W = west, E = east.

While Davis et al. (2011) focused on broad regional differences in the composition of $PM_{2.5}$ and its potential role in explaining the heterogeneity in $PM_{2.5}$-mortality risk estimates, Baxter et al. (2013) focused specifically in trying to identify potential contributors to the city-to-city differences in risk estimates observed in multicity epidemiologic studies. Baxter et al. (2013) conducted a semiquantitative analysis focusing on $PM_{2.5}$ component and gaseous pollutant concentrations to gain a better understanding

of their relationship with $PM_{2.5}$ mass, and their potential influence on $PM_{2.5}$-mortality risk estimates. Focusing on the results from a study of 27 U.S. cities conducted by Franklin et al. (2007), Baxter et al. (2013) explored city-specific air pollution characteristics for the two cities in each region of the U.S. with the largest and smallest $PM_{2.5}$-mortality risk estimates (i.e., Northeast: Boston, MA [largest] and Pittsburgh, PA; South: Memphis, TN [largest] and Birmingham, AL; Midwest: Milwaukee, WI [largest] and Detroit, MI; West: San Diego, CA [largest] and Riverside, CA). To explore air pollution characteristics of each city, the authors examined (1) percent contribution of each $PM_{2.5}$ component to $PM_{2.5}$ mass; (2 and 3) Spearman correlation and COD between each city pair and pollutant (21 $PM_{2.5}$ components, $PM_{2.5}$ mass, and gaseous pollutants); (4) Spearman correlation between each $PM_{2.5}$ component and gaseous pollutant and $PM_{2.5}$ mass in each city; and (5) composition of air pollution mixtures in each city to identify whether sources differ between cities by conducting a principal component analysis (PCA) including both PM and gaseous pollutant data. Although there were some differences between cities, this analysis did not identify one component or group of components that could explain the difference between city pairs. Additionally, in the source-based analysis, differences were observed between cities when focusing on local sources such as motor vehicle and industry, but one or more sources were not identified that could explain the difference in risk estimates between cities. Overall, the study by Baxter et al. (2013) indicates some differences in $PM_{2.5}$ composition and sources between cities, but also demonstrates that city-to-city differences in $PM_{2.5}$-mortality risk estimates are not limited to $PM_{2.5}$ source and composition differences.

11.1.6.3.2 Exposure Factors

Many studies that have examined heterogeneity in $PM_{2.5}$-mortality risk estimates often examine whether specific city characteristics modify the association. This examination occurs in a second-stage analysis that focuses on the distribution of a factor (e.g., percentage poverty) across cities and how risk changes moving from the low end to the high end of the distribution. Lippmann et al. (2013a) used this more traditional approach, but focused on a suite of city-specific variables (i.e., land-use, port-, and traffic-related data) that could reflect exposure differences. The evidence indicated that port berth volume within 60 miles of a city along with the sum of road lengths within a city increased the risk of $PM_{2.5}$-related mortality. There was also evidence that percent of a city developed and percent of a city with wetland positively increased risk, but with greater uncertainty. The relationship between $PM_{2.5}$-mortality risk and port berth volume is supported by the negative relationship with distance to large port. The results of Lippmann et al. (2013a) provides evidence that city-specific factors that may influence exposure can influence the $PM_{2.5}$-mortality relationship across cities.

Unlike Lippmann et al. (2013a) where the focus was on community-level factors that may modify the $PM_{2.5}$-mortality relationship, Baxter and Sacks (2014), which in some respect is an expansion of Baxter et al. (2013), focused on exploring whether there are city-specific exposure profiles that may have a role in explaining the observed heterogeneity. Using data from the American Housing Survey (AHS) for

94 Core-Based Statistical Areas (CBSAs) with a population greater than 500,000 from 2001−2005, the authors used k-means clustering to examine whether there were unique CBSA clusters based on residential infiltration factors (i.e., percent of homes with central AC, mean year home was built, and mean home size) and both residential infiltration factors and commuting factors (i.e., mean in-vehicle commuting time and mean in-vehicle commuting distance). The residential infiltration factor analysis identified five clusters, with a large number of the cities in clusters 1 (N = 24) and 3 (N = 40). The main difference between these clusters were the mean home age was slightly older for cluster 1, while there was a greater percent of central AC in cluster 3. There was evidence of a geographic pattern in the clustering of cities as reflected in Figure 11-9. The combination of residential infiltration and commuting factors resulted in the identification of 10 clusters. Across clusters, only two clusters had more than 11 CBSAs, clusters 8 and 9, which primarily differed by percent of homes with central AC. Cities with shorter commuting times were found to also have shorter commuting distances. Although not as pronounced as the residential infiltration analysis there tended to be a geographic pattern in the residential infiltration and commuting factor analysis (Figure 11-9). In Baxter and Sacks (2014) 66 of the CBSAs encompassed cities included in NMMAPS, therefore, the cluster analysis results were compared to city-specific PM_{10}-mortality risk estimates from NMMAPS. Recognizing the potential differences in infiltration between $PM_{2.5}$ and PM_{10}, given that $PM_{2.5}$ comprises varying proportions of PM_{10}, the results provide some evidence that cities with older homes and a smaller percent of central AC have higher risk estimates compared to cities with newer homes and a larger percent of central AC. Although the addition of commuting factors to the cluster analysis could reveal some additional exposure nuances between cities, the small number of CBSAs in each cluster complicates the interpretation of the combined analyses. Overall, the results of Baxter and Sacks (2014) provide initial evidence that certain differences in exposure characteristics between cities may also contribute to explaining the city-to-city heterogeneity in $PM_{2.5}$-mortality risk estimates.

Figure 11-9 Maps of Core-Based Statistical Areas (CBSAs) by cluster based on (A) residential infiltration factors and (B) residential infiltration and commuting factors.

Baxter et al. (2017) built off the cluster analysis detailed in Baxter and Sacks (2014), and used only the residential infiltration-based clusters as a means to explore whether there are differences in the $PM_{2.5}$-mortality association across clusters and if the clusters explain the observed heterogeneity. In the analysis, 77 U.S. cities were grouped into five clusters based on prevalence of central air conditioning, mean year home was built, and mean size of home. Focusing on those clusters where the number of cities included was greater than 5, there is some evidence of differences in $PM_{2.5}$ mortality risk estimates that could be attributed to differential exposure as a result of residential infiltration. For example, clusters 1 and 3 were representative of smaller homes, but with differing age and percent of air conditioning. Cluster 3 homes had a higher percentage of central air conditioning and were newer than cluster 1, but the risk estimates in both clusters were the smallest across clusters (cluster 1: −0.01% [95% CI: −0.31, 0.29]; cluster 3: 0.25 [95% CI: −0.15, 0.65]). Cluster 4, which was representative of larger homes that were older with a moderate percentage of central air conditioning (i.e., 55.7%) had the largest risk estimate (0.66% [95% CI: 0.35, 0.97]). These results are consistent with previous studies that have demonstrated that air exchange rates are higher in larger and older homes, resulting in increased exposures to ambient

PM (Section 3.4.1.1). In a second-stage analysis, the authors further examined the role of the clusters in explaining the observed heterogeneity and whether the individual residential infiltration factors alone contributed to the heterogeneity. Baxter et al. (2017) reported that cluster assignment explained 6% of the observed heterogeneity, and that only larger home size modified the $PM_{2.5}$-mortality association, which is consistent with the results of the main cluster analysis.

11.1.7 Evaluation of Exposure Assessment Techniques

As described in the previous section, a number of factors have been considered in an attempt to explain the heterogeneity in $PM_{2.5}$-mortality risk estimates. An underlying factor not discussed in the previous section is the potential role of exposure assessment and exposure misclassification (see Section 3.4.2). Traditionally, air pollution epidemiology studies have relied upon single monitors or the average of multiple monitors over some geographic extent (e.g., county) to assign exposure. Recent studies have examined the influence of distance to monitor on the $PM_{2.5}$-mortality association. Additionally, new and innovative approaches have been developed that use ensemble approaches to combine air pollution data from a number of sources including ambient monitors and satellite data, as well as model predictions in an attempt to obtain a more refined estimate of exposure. The following section discusses these approaches and how this information further informs the $PM_{2.5}$-mortality relationship.

11.1.7.1 Monitor Representativeness

Recent studies by Davis et al. (2011), Kloog et al. (2013), Kim et al. (2015), and Di et al. (2017a) conducted sensitivity analyses to examine the potential influence of distance to monitor on the relationship between short-term $PM_{2.5}$ exposure and mortality. These types of analyses can provide information on exposure assessment that may influence the city-to-city or regional heterogeneity observed in multicity epidemiologic studies.

As part of their analysis examining if there are broad $PM_{2.5}$ composition differences between regions, Davis et al. (2011) also explored the representativeness of ambient monitors to reflect population exposure. Both on an individual city level as well as the broad regional classifications identified (i.e., north versus south, and east versus west), the authors examined the percent of the population residing within 1 km, 5 km, 10 km, and 15 km from an AQS monitor. Less than 50% of the population across almost all cities resided within 5 km of a monitor. Interestingly, of the 20 cities with populations over 1 million people, almost half of the cities had up to 20% of the population residing greater than 15 km of an AQS monitor. In the regional designations, a larger percent of people was closer to monitors at all distances for both the East and North designations. The 2009 PM ISA (U.S. EPA, 2009) presented data for intermonitor correlation versus distance between monitors to examine the influence of distance to

monitor on exposure assessment (see Section 3.4.2.2). Correlations of approximately Pearson $R = 0.90$ were reported for intermonitor distances of 15 km in three cities (Boston, Pittsburgh, and Los Angeles) with correlations largely above 0.8 at distances of 50 km in Boston in Pittsburgh. These findings indicate that temporal variability of $PM_{2.5}$ concentrations are often similar over urban scales. Therefore, large errors in the exposure time-series are not anticipated across large distances for the cities included in Davis et al. (2011).

Recent studies examined the influence of distance to monitor on the association between short-term $PM_{2.5}$ exposure and mortality. Kloog et al. (2013) examined the impact of distance to monitor on the daily $PM_{2.5}$-mortality association as part of a study conducted in Massachusetts. Within this study, daily $PM_{2.5}$ concentrations were predicted to 10 × 10 km grid cells using satellite data that were calibrated with ground-level $PM_{2.5}$ measurements. Additionally, land-use regression and weather variables were used to predict $PM_{2.5}$ concentrations on days where AOD values were not available. In a sensitivity analysis, the authors examined associations based on distance to monitor, defined as greater than or less than 20 km from an ambient monitor. In models that included an interaction term for distance to monitor, Kloog et al. (2013) reported a 4.5% increase in mortality (95% CI: 2.6, 6.5) near a monitor and 1.4% increase in mortality (95% CI: 0.8, 2.0) far from a monitor at lag 0−1, compared with a 2.8% increase in mortality (95% CI: 2.0,3.5) across the study population. Di et al. (2017a) also conducted a sensitivity analysis examining $PM_{2.5}$-mortality associations based on the nearest monitor within 50 km. In the main analysis, the authors predicted $PM_{2.5}$ and O_3 concentrations to 1 km × 1 km grid cells based on the combination of ambient monitoring data, satellite measurements, land-use data, and chemical transport modeling. $PM_{2.5}$ exposures were assigned to the zip code level and in a model that adjusted for O_3, Di et al. (2017a) reported a 1.05% increase (95% CI: 0.95, 1.15) in all-cause mortality at lag 0−1 days within the Medicare population. In the nearest monitor analysis, the authors also reported a positive association, but it was smaller in magnitude (0.83% [95% CI: 0.73, 0.93]; lag 0−1), which is consistent with the results of Kloog et al. (2013) and indicative of some degree of exposure misclassification at distances further from monitors. However, Kim et al. (2015) as part of the DASH study in Denver, CO, examined the $PM_{2.5}$-mortality association at 10 km and 20 km buffers around a single monitor and found no evidence of a difference in the association across buffers. As discussed in Davis et al. (2011) and in Section 2.5.1.2.1 this could reflect the spatial and temporal characteristics of $PM_{2.5}$ in Denver, which may differ from those observed in Kloog et al. (2013) in Massachusetts and Di et al. (2017a) nationally.

11.1.7.2 Urban versus Rural Locations

As detailed in Chapter 3, new and innovative statistical approaches have been developed to obtain more refined exposure estimates, particularly in areas that do not have ambient monitors (i.e., rural locations). The studies by Kloog et al. (2013), Shi et al. (2015), and Lee et al. (2015c) all employed some derivation of a similar approach to estimate $PM_{2.5}$ concentrations that relied upon satellite measurements.

The question that often arises from studies such as these is: How well does the method employed capture $PM_{2.5}$ concentrations in areas that do not have monitors?

Of the studies conducted to date, only Lee et al. (2015c) explored the difference between urban and rural $PM_{2.5}$-mortality associations using both the modeled data, which incorporated satellite measurements, and the nearest ambient monitor across three southeastern U.S. states. Using the modeled $PM_{2.5}$ data, the authors reported evidence of a larger association in rural compared to urban locations, but when assigning exposure using data from ambient $PM_{2.5}$ monitors, the rural location association remained positive although it was attenuated (Figure 11-10). Overall, the results from Lee et al. (2015c) provide some evidence for potential differences in $PM_{2.5}$-mortality associations between urban and rural locations, but uncertainties remain due to the relative sparseness of monitors in rural locations and the known differences in $PM_{2.5}$ sources between locations.

Figure 11-10 Percent increase in mortality at lag 0−1 for a 10 μg/m³ increase in 24-hour average $PM_{2.5}$ concentrations based on location of residence using modeled and monitored $PM_{2.5}$ concentrations.

11.1.8 Timing of Effects and Exposure Metrics

11.1.8.1 Lag Structure of Associations

Within the 2009 PM ISA, the studies evaluated indicated that the effect of short-term $PM_{2.5}$ exposure on mortality was immediate, occurring within the first few days after exposure, with the strongest evidence, in terms of magnitude and precision of the associations, in the range of 0 to 1 day.

However, these studies defined the lags to examine a priori and often in accordance with the 1-in-3 or 1-in-6 day sampling schedule of ambient $PM_{2.5}$ monitors. Additionally, these mortality studies examined associations with $PM_{2.5}$ using a 24-hour average exposure metric, resulting in the inability to determine whether subdaily exposure metrics (e.g., 1-hour max) capture other exposures of concern. Some studies published since the completion of the 2009 PM ISA have conducted more extensive examinations of the lag structure of associations for short-term $PM_{2.5}$ exposures and mortality, focused on subdaily exposure metrics to understand the role of peak $PM_{2.5}$ concentrations on the $PM_{2.5}$-mortality relationship, and examined whether the risk of mortality attributed to short-term $PM_{2.5}$ exposure has changed over time.

The studies evaluated in the 2009 PM ISA did not conduct a systematic evaluation of the lag structure of associations between short-term $PM_{2.5}$ exposure and mortality, but reported evidence of consistent, positive associations within the first few days after exposure (i.e., 0−1 lag days) (U.S. EPA, 2009). Recent studies have conducted analyses aimed at understanding the timing of effects between short-term $PM_{2.5}$ exposure and mortality. Studies have ranged in their level of evaluation from examining multiple individual or multiday lags to more systematically examining whether there is evidence of immediate (e.g., lag 0−1 days), delayed (e.g., lag 2−5 days), or prolonged (e.g., lag 0−5 days) effects. However, a number of studies do not provide the information necessary to systematically evaluate the timing of the relationship between $PM_{2.5}$ exposure and mortality. For example, in a study conducted in the Netherlands, Janssen et al. (2013) examined single-day lags ranging from 0 to 3 days, along with the inclusion of a lag encompassing the average of 0−6 days. By not including information on lag days 4, 5, and 6 only the single-day lag information can be interpreted because it is not possible to differentiate whether considering a longer lag is reasonable.

The evidence from experimental studies can provide information on the biological plausibility of the timing between exposure and effect. In the case of cardiovascular mortality, which encompasses ~33% of total (nonaccidental) mortality (NHLBI, 2017), it is well characterized that short-term $PM_{2.5}$ exposure results in rather immediate cardiovascular responses (Section 6.1.14.3), providing biological plausibility for the focus of most $PM_{2.5}$-mortality studies on shorter windows of exposure, in the range of 0 to 2 days. However, the evidence for a respiratory effect in response to short-term $PM_{2.5}$ exposure has been found to be more delayed, which provides biological plausibility for examining associations with respiratory mortality at longer lags (Section 5.1.10.3). Although the discussion of lag structure of associations for cause-specific mortality will be detailed in the respective cardiovascular and respiratory chapters, the biological plausibility of the timing of effects for cardiovascular and respiratory mortality provide the basis for focusing the discussion on the lag structure of associations on those studies that: evaluate a series of single-day lags (e.g., lags 0 to 3 days); conduct a systematic evaluation of different lags (e.g., single-day versus distributed or average of multiple days); and include all single days evaluated in the distributed or multiday average lags (i.e., if a study examines a distributed or multiday average lag of 0−6 days it also examines single-day lags of 0 to 6 days).

Most of the recent studies that examined the lag structure of associations for the $PM_{2.5}$-mortality relationship either conducted analyses of single-day lags over multiple days or various iterations of multiday lags (e.g., 0−1, 0−2, 0−3, etc.). As part of the NPACT study, Lippmann et al. (2013b) examined single-day lags ranging from 0 to 3 days. In all-year analyses, the strongest associations, in terms of magnitude and precision, with total (nonaccidental) mortality were at lags 0 and 1 day, with associations persisting in the warm season and no evidence of an association in the cold season. The results of Lippmann et al. (2013b) are consistent with the pattern of associations observed in other multicity studies that also examined a series of single-day lags (Di et al., 2017a; Stafoggia et al., 2017; Janssen et al., 2013). Di et al. (2017a) examined single-day lags of 0 to 4 days and compared these results to the main analysis that used a multiday lag of 0−1 days. It is important to note that the main analysis as well as these sensitivity analyses were based on a model that also adjusted for O_3. Across the single-day lags, results support an immediate effect as reflected by largest magnitude of an association for lag 0 and 1 day (~ 0.75% increase in all-cause mortality), but these associations were smaller in magnitude to the main analysis that used the multiday lag of 0−1 days (1.05% [95% CI: 0.95, 1.15]). When examining the other single-day lags, Di et al. (2017a) reported a much smaller association at lag 2 (~0.25% increase), with no evidence of an association at lag 3 and 4. In an examination of single-day lags (i.e., 0 to 3 days), Janssen et al. (2013) reported rather immediate effects with associations similar in magnitude (0.8−1.0%) across each of the single-day lags. An examination of single-day lags ranging from 0 to 10 days in a study of eight European cities reported the strongest association at lag 1 (Stafoggia et al., 2017). The pattern of associations observed across studies that examined a series of single-day lags is consistent with the results reported by Lee et al. (2015a) that examined a series of multiday lags and observed the strongest associations for total (nonaccidental) mortality at lag 0−1, but associations remained positive when examining multiday lags up to 0−4 days.

In the MED-PARTICLES Project, Samoli et al. (2013) conducted a systematic evaluation of the lag structure of associations by examining whether there was evidence of an immediate (lag 0−1), delayed (lag 2−5), or prolonged (lag 0−5) $PM_{2.5}$-mortality effect as well as examining the pattern of associations over lags 0 to 7 days in a polynomial distributed lag model. The authors reported a 0.55% increase in total (nonaccidental) mortality (95% CI: 0.27, 0.84) at lag 0−1, a 0.51% increase (95% CI: 0.07, 0.96) at lag 2−5, and a 0.70% increase (95% CI: 0.22, 1.18) at lag 0−5. Although the 0−5 lag shows the association largest in magnitude, the 0- to 1-day lag comprises a large amount of this effect. A closer examination of associations on a day-to-day basis through the polynomial distributed lag model shows evidence of the strongest associations within the range of 1 to 3 days (quantitative results not presented). The combination of the multi- and single-day lag analyses provides further support for the $PM_{2.5}$-mortality association being strongest within the first few days after exposure.

11.1.8.2 24-Hour Average versus Subdaily (Peak) Exposures

Most of the studies conducted to date have examined the association between short-term $PM_{2.5}$ exposure and mortality using 24-hour average exposure metrics. A few recent single-city studies examined alternative exposure metrics to further examine the relationship between short-term $PM_{2.5}$ exposure and mortality. In a study conducted in Oslo, Norway that estimated $PM_{2.5}$ concentrations using a dispersion model Madsen et al. (2012) used the traditional 24-hour average exposure metric along with one representative of peak exposures (i.e., the hourly average two daily rush hour periods; 08:00–10:00 and 15:00–17:00). Within this study mean peak concentrations were approximately 23 $\mu g/m^3$, while 24-hour average concentrations were 15.1 $\mu g/m^3$. The authors observed the same pattern of associations across the single and multiday lags examined (i.e., lags 4 and 5, and 0−4 and 0−5 days) for the 24-hour average and peak exposure metric with the magnitude being slightly larger for the 24-hour average metric (quantitative results not provided). Although Lin et al. (2016) examined peak and 24-hour average $PM_{2.5}$ exposures that were much higher (i.e., 1-hour max = 66.9 $\mu g/m^3$ and 24-hour average = 46.4 $\mu g/m^3$) than those reported in Madsen et al. (2012), the results from this study can further inform our understanding of alternative exposure metrics. Unlike Madsen et al. (2012) which used $PM_{2.5}$ concentrations predicted from a dispersion model, $PM_{2.5}$ concentrations in Lin et al. (2016) were measured over 11 ambient monitors throughout Guangzhou, China. In analyses of peak and 24-hour average $PM_{2.5}$ exposures and cardiovascular mortality at single day lags ranging from 0 to 5 days, and multiday lags from 0 to 3 days, the authors observed a consistent pattern of associations across lags for both exposure metrics, with the magnitude of the association often larger in models with the 24-hour average metric. The results of Lin et al. (2016) are consistent with those observed in Madsen et al. (2012), which collectively provide initial evidence that when comparing subdaily and 24-hour average exposure metrics, the 24-hour average exposure metric is consistently associated with mortality.

11.1.9 Alternative PM Size Fractions and Exposure Metrics

While most studies that examine the relationship between short-term $PM_{2.5}$ exposure and mortality focus on $PM_{2.5}$ mass, some studies have examined alternative exposure metrics, such as particle number concentration (NC), surface area concentration (SC), and mass concentration (MC) for PM size fractions smaller than $PM_{2.5}$ but larger than 100 nm. Particles smaller than 100 nm will be discussed in Section 11.5. To date, only a few studies examined PM size fractions smaller than 2.5 µm, and often these size fractions are included in studies that examine UFP exposure and mortality (Section 11.4.1). Across studies, generally positive associations were observed for particles >100 nm for NC, and <1.0 µm for SC and MC (See (U.S. EPA, 2018a)), which supports the larger body of evidence demonstrating a consistent, positive association between short-term $PM_{2.5}$ exposure and mortality. However, these studies are conducted over a short duration and are limited to two locations (i.e., China (Meng et al., 2013; Leitte et al., 2012; Breitner et al., 2011) and Spain (Pererz et al., 2009)). Additionally, although these studies report

generally positive associations it remains difficult to directly compare results from studies that use a NC or SC metric with the traditional mass based exposure metric.

11.1.10 Concentration-Response (C-R) Relationship and Threshold Analyses

Previous reviews of PM including the 2004 PM AQCD (U.S. EPA, 2004) along with the 2009 PM ISA (U.S. EPA, 2009) have highlighted the difficulty associated with examining the shape of the PM-mortality concentration-response (C-R) relationship and whether a threshold exists. Specifically, the 2004 AQCD and 2009 PM ISA stated that conducting C-R and threshold analyses is challenging due to the "(1) limited range of available concentration levels (i.e., sparse data at the low and high end); (2) heterogeneity of [at-risk] populations [between cities]; and (3) influence of measurement error" (U.S. EPA, 2004). Even with these inherent limitations, studies have continued to examine the PM-mortality C-R relationship and whether a threshold exists. In the 2009 PM ISA, the examination of the PM-mortality C-R relationship was limited to studies of PM_{10}. Within the multicity studies examined, there was evidence of a linear no-threshold C-R relationship between short-term PM exposures and mortality with some evidence of differences in the shape of the C-R curve across cities. A major limitation of the C-R analyses conducted to date has been the reliance on PM_{10} data and the limited amount of data available to examine the shape of the C-R curve at the low end of the concentration distribution. Recent studies conducted in the U.S. (Di et al., 2017a; Lee et al., 2015c; Shi et al., 2015) and Europe (Samoli et al., 2013) provide information specifically on the C-R relationship between short-term $PM_{2.5}$ exposures and mortality in different regions of the world and at $PM_{2.5}$ concentrations at the lower end of the distribution.

In a study of states in the New England region of the U.S., Shi et al. (2015) conducted two analyses to address (1) whether associations are observed at concentrations <30 $\mu g/m^3$ and (2) the shape of the PM-mortality C-R relationship at concentrations <30 $\mu g/m^3$. In the analysis restricted to person-time with $PM_{2.5}$ concentrations <30 $\mu g/m^3$ Shi et al. (2015) reported associations similar in magnitude (2.14% [95% CI: 1.33, 2.95]) to those observed in the full cohort that included $PM_{2.5}$ concentrations >30 $\mu g/m^3$ (2.14% [95% CI: 1.38, 2.89]). Using the restricted data set, Shi et al. (2015) then examined the shape of the C-R relationship between short-term $PM_{2.5}$ concentrations and mortality by fitting a penalized regression spline where the degrees of freedom (df) of the spline were selected by generalized cross-validation. The authors reported no evidence of deviation from linearity, but had less confidence in the shape of the curve at concentrations <5 $\mu g/m^3$ due to wider confidence intervals (Figure 11-11).

Figure 11-11 Concentration-response relationship between short-term $PM_{2.5}$ concentrations and mortality (lag 0−1) in an analysis restricted to person time with daily $PM_{2.5}$ concentrations <30 µg/m³.

Di et al. (2017a) examined the C-R relationship focusing on questions similar to those examined by Shi et al. (2015), but in a national analysis of the Medicare population. In a copollutant model with O_3 the authors examined: (1) whether associations are observed at $PM_{2.5}$ concentrations <25 µg/m³, and (2) the shape of the PM-mortality C-R relationship, particularly at concentrations <25 µg/m³. In the low exposure analysis, Di et al. (2017a) reported an association larger in magnitude (1.61 [95% CI: 1.48, 1.74]; lag 0−1) than the main analysis (1.05% [95% CI: 0.95, 1.15]; lag 0−1), indicating a steeper slope at lower $PM_{2.5}$ concentrations. The results of the low exposure analysis were confirmed when examining the shape of the C-R curve using penalized splines for both $PM_{2.5}$ and O_3, which reported evidence of an almost linear relationship with no evidence of a threshold and a steeper slope at concentrations <25 µg/m³ (Figure 11-12). While the low exposure results of Di et al. (2017a) differ from those of Shi et al. (2015),

this could be a reflection of the populations of the studies encompassing different age ranges (i.e., individuals over the age of 65, and the entire population, respectively).

Figure 11-12 Two-pollutant analysis of the $PM_{2.5}$ concentration-response (C-R) curve with penalized splines for both $PM_{2.5}$ and O_3 to examine the percent increase in daily mortality at lag 0−1 days.

Lee et al. (2015c) confirmed the findings of Shi et al. (2015) and Di et al. (2017a) that $PM_{2.5}$-mortality associations persist at low ambient $PM_{2.5}$ concentrations by conducting a subset analysis focusing on three southeastern U.S. states. The authors examined the association between short-term $PM_{2.5}$ exposure and mortality by limiting the dataset to zip codes where the predicted annual $PM_{2.5}$ concentrations were less than 12 µg/m^3 and in a separate analysis focused on ZIP codes where predicted 24-hour average $PM_{2.5}$ concentrations were less than 35 µg/m^3. In the full cohort the authors reported a 1.56% increase in mortality (95% CI: 1.19, 1.94) at lag 0−1. In the cut-point analyses focusing on the annual and daily cutpoints, Lee et al. (2015c) reported a 2.06% (95% CI: 1.97, 2.15) and 2.08% (95% CI: 1.99, 2.17) increase in mortality, respectively, providing evidence that $PM_{2.5}$-mortality associations remain and may be larger in magnitude at low $PM_{2.5}$ concentrations.

While Shi et al. (2015), Lee et al. (2015c), and Di et al. (2017a) examined the shape of the C-R relationship between short-term $PM_{2.5}$ exposure and mortality across a distribution of data, Samoli et al. (2013) focused exclusively on whether there is evidence of a threshold at specific concentrations. As part of the MED-PARTICLES project, the authors examined threshold values ranging from 0 to 35 µg/m^3 at increments of 5 µg/m^3 across the 10 Mediterranean cities included in the study. The threshold model

assumed the risk of mortality due to short-term $PM_{2.5}$ exposure was zero below the threshold value. Evidence of a threshold was examined in each city by computing the deviance of the fitted model for each threshold value, the authors then computed an average deviance across all cities. The deviance for each threshold value was then examined to determine whether any threshold values minimized the mean deviance. Samoli et al. (2013) did not observe any evidence of a threshold, with the models assuming no threshold reporting the lowest mean deviance, and subsequently being considered the "best-fitting" models. Although the 24-hour average $PM_{2.5}$ concentrations observed in the MED-PARTICLES cities were much higher than the $PM_{2.5}$ concentrations observed in Shi et al. (2015), the threshold analysis in Samoli et al. (2013) focusing on daily concentrations below 35 $\mu g/m^3$ provides additional support for a linear C-R relationship at concentrations relevant to U.S. cities.

Although difficulties remain in assessing the shape of the $PM_{2.5}$-mortality concentration-response relationship, as identified in the 2009 PM ISA, and studies have not conducted systematic evaluations of alternatives to linearity, recent studies continue to provide evidence of a no-threshold linear relationship, with less confidence at concentrations lower than 5 $\mu g/m^3$. Additionally, those studies that conducted analyses focused on examining associations at lower $PM_{2.5}$ concentrations provide initial evidence indicating that associations persist and may be larger in magnitude (i.e., a steeper slope) at lower $PM_{2.5}$ concentrations.

11.1.11 Associations between $PM_{2.5}$ Sources and Components and Mortality

The 2009 PM ISA examined the relationship between both $PM_{2.5}$ components and sources and individual health outcomes (e.g., mortality) and effects (e.g., blood pressure), as well as collectively across health outcomes, to assess whether any one source or component was more strongly related to a health outcome or effect. At the completion of the 2009 PM ISA, it was not evident that any one component or source was more strongly related to mortality, which was consistent with the broader conclusion on sources and components (U.S. EPA, 2009). Recent studies that examine both the relationship between short-term exposures to $PM_{2.5}$ components along with $PM_{2.5}$ mass provide additional evidence on whether $PM_{2.5}$ mass or an individual $PM_{2.5}$ component or source is more strongly associated with mortality.

11.1.11.1 $PM_{2.5}$ Components

The examination of the relationship between $PM_{2.5}$ components and mortality can generally be divided into two types of analyses: (1) those that examine whether specific components modify the $PM_{2.5}$-mortality association or (2) those that examine whether an individual component is associated with mortality and potentially a better indicator of PM toxicity compared to $PM_{2.5}$ mass. Although

approach (1) is considered one of the techniques used to assess component toxicity as detailed in Mostofsky et al. (2012) these studies are often used to examine heterogeneity in $PM_{2.5}$-mortality risk estimates. As a result, the focus of this section is on those techniques that fall under approach (2), which includes assessing $PM_{2.5}$ component effect by component concentration, component proportion, component concentration adjusted for $PM_{2.5}$ mass, component residual, or $PM_{2.5}$ residual (Mostofsky et al., 2012). Multicity $PM_{2.5}$ mortality studies detailed in the 2009 PM ISA examined associations with individual components (Ostro et al., 2008; Ostro et al., 2007), and indicated that a number of components are associated with mortality. However, there were limitations in the air quality data (i.e., 1-in-3 or 1-in-6 sampling of $PM_{2.5}$ components) and only a small number of studies had been conducted that examined the relationship between $PM_{2.5}$ components and mortality (U.S. EPA, 2009).

Since the completion of the 2009 PM ISA (U.S. EPA, 2009), a growing number of studies have examined the relationship between short-term exposure to $PM_{2.5}$ components and mortality. These studies continue to support the conclusions of the 2009 PM ISA that many components are associated with mortality and there is no evidence that any one component is more strongly associated with mortality than $PM_{2.5}$ mass. The recent multicity studies and U.S.-based single-city studies are detailed in Table 11-3 along with study specific details including statistical approach used to assess the $PM_{2.5}$ component effect and the $PM_{2.5}$ components examined.

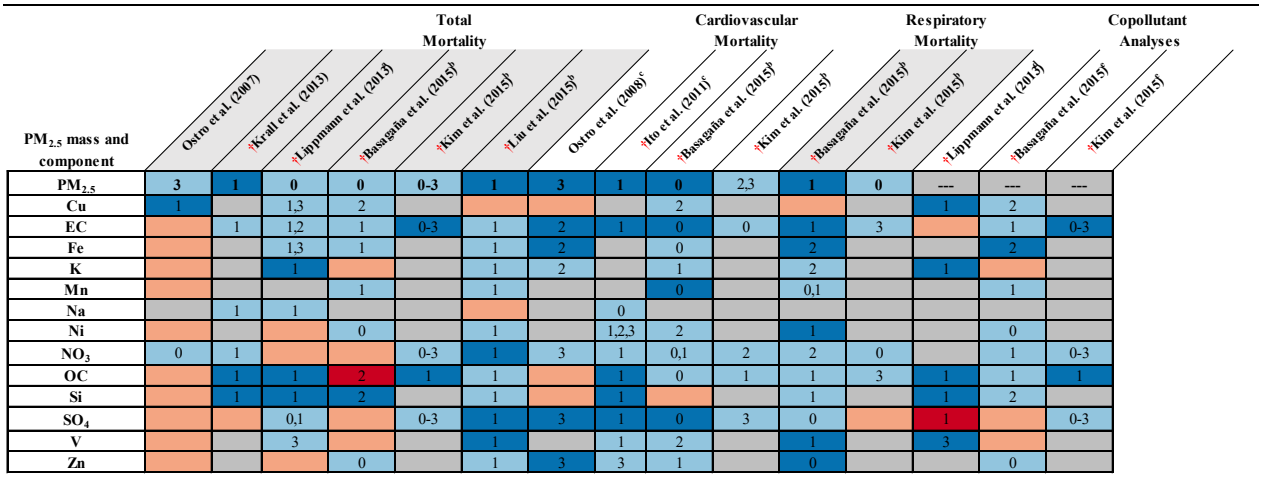
†Studies published since the 2009 PM ISA.

As detailed in Table 11-3 and throughout the text that follows, the evaluation of the association between $PM_{2.5}$ components and mortality is complicated by the different methods applied across studies. Overall, the results for individual $PM_{2.5}$ components across studies are generally more imprecise than the results for $PM_{2.5}$ (i.e., much wider confidence intervals, often including the null value), which make the individual results, as well as results across studies, more difficult to interpret. As such, for the purposes of characterizing results with respect to $PM_{2.5}$ components a different convention is employed to evaluate the pattern of associations across studies. Specifically, risk estimates from studies are classified into four categories in Figure 11-13 and Figure 11-14: (1) statistically significant positive associations; (2) positive

associations, regardless of width of the confidence interval; (3) null or negative association; and (4) statistically significant negative association. Figure 11-13 and Figure 11-14 summarize the results from studies that examined associations between short-term $PM_{2.5}$ mass and $PM_{2.5}$ components that will be evaluated in the following section.



[a]Lippmann et al. (2013a) results representative of median interquartile range increase in individual $PM_{2.5}$ component concentrations for the 64 cities combined.

[b]Results representative of an interquartile range increase in individual $PM_{2.5}$ component concentrations.

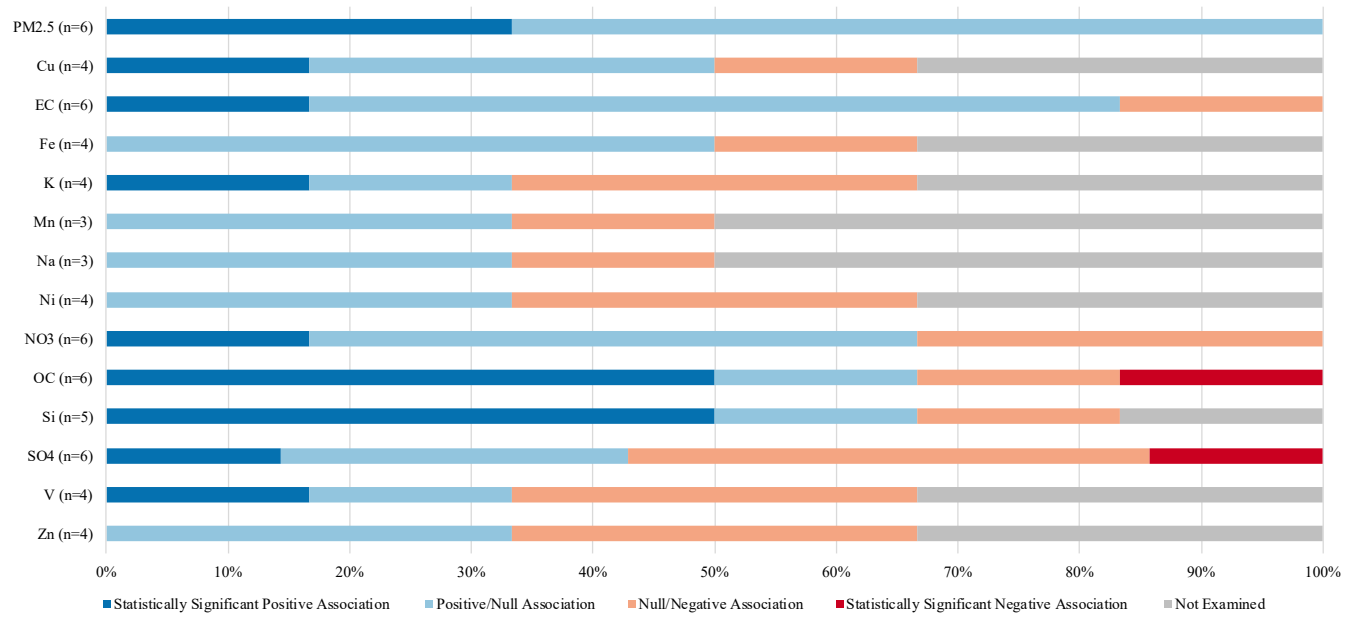
[c]Studies only examined $PM_{2.5}$ component associations with cardiovascular mortality.

[d]Lippmann et al. (2013a) results representative of median interquartile range increase in individual $PM_{2.5}$ component concentrations for the 64 cities combined in copollutant model with $PM_{2.5}$.

[e]Basagaña et al. (2015) results using the $PM_{2.5}$ component residual method detailed by Mostofsky et al. (2012).

Note: †$PM_{2.5}$ component studies published since the 2009 PM ISA. $PM_{2.5}$ row = lag(s) at which association observed between short-term $PM_{2.5}$ exposure and mortality; $PM_{2.5}$ components rows = lag(s) at which association observed. Dark blue = study reported statistically significant positive association; Light blue = study reported a positive association regardless of width of confidence intervals; Light orange = study reported null or negative association; Red = study reported statistically significant negative association; Gray = study did not examine individual component. Only those $PM_{2.5}$ components that were examined in at least three studies that included results for total (nonaccidental) mortality are included in this table.

Figure 11-13 Heat map of associations observed between short-term $PM_{2.5}$ and $PM_{2.5}$ components exposure and mortality in multi- and single-city studies.



N = number of studies that provided an estimate for $PM_{2.5}$ mass and individual $PM_{2.5}$ components.

Note: Bars represent the percent of associations across studies for $PM_{2.5}$ mass or $PM_{2.5}$ components detailed in Figure 11-13 that are statistically significant positive (dark blue), positive/null (light blue), null/negative (light orange), statistically significant negative (red), or not examined (gray).

Figure 11-14 Distribution of total (nonaccidental) mortality associations for $PM_{2.5}$ and $PM_{2.5}$ components examined in studies detailed in Figure 11-13.

Single Component Models

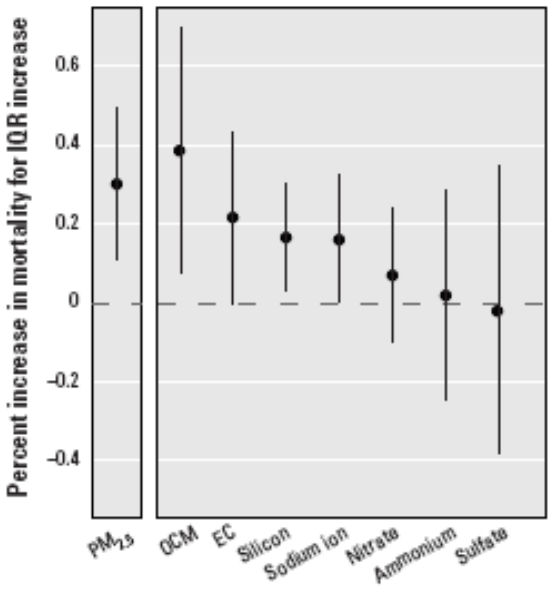
At the completion of the 2009 PM ISA, most studies that examined the association between short-term exposure to $PM_{2.5}$ components and mortality consisted of statistical models that examined component-mortality associations one at a time. Although informative, these studies are often difficult to interpret because they do not account for the individual component being part of $PM_{2.5}$ mass. Additionally, although often not reported, the correlations between individual $PM_{2.5}$ components and $PM_{2.5}$ mass are often moderate ($r = 0.4–0.7$) to high ($r > 0.7$), which complicates the interpretation of the single-component model results. Recent multi- and single-city studies have continued to examine $PM_{2.5}$ component-mortality associations in single component models, but the addition of seasonal analyses for some studies have attempted to gain a broader understanding of how $PM_{2.5}$ mass and overall composition may change over the course of the year and affect health.

Multicity studies conducted by Lippmann et al. (2013a) as part of the NPACT study and Krall et al. (2013) in 72 U.S. cities, both primarily focused on single-component models to assess the relationship between $PM_{2.5}$ components and mortality. Lippmann et al. (2013a) examined the association between short-term exposure to $PM_{2.5}$ components, along with sources (see Section 11.1.11.2), across 64 U.S. cities. The components selected to be examined were based on analyses of measurements obtained, in

reference to both the detection limit and fraction of readings equaling zero; monitor-to-monitor correlations for a subset of cities; and toxicological considerations (Lippmann et al., 2013a). In the main analyses, the authors did not use measured component data, but instead calculated the daily deviation from the monthly mean in an attempt to "reduce the influence of the seasonal cycles of pollutants on the overall associations" (Lippmann et al., 2013a). In single-component models in an all-year analysis, the strongest associations were for Cu, K, OC, Si, and V although at different lags ranging from 1 to 3 days, while the $PM_{2.5}$ association was positive at lag 0 (Figure 11-13). In seasonal analyses, the $PM_{2.5}$ association was strongest in the warm season at lag 0 with no evidence of an association in the cold season. Across components strong positive associations were only observed at lag 0 for Na, NO_3^-, and SO_4^{2-}, while other components were found to be positively associated at other lags including: EC, K, Na, OC, Pb, Si, and V. A different pattern of associations was observed in the cold season with evidence of positive associations across lags for As, Cu, EC, K, OC, Se, and Si. The different lag structure of associations for the individual components compared to $PM_{2.5}$ mass complicates the interpretation of the individual component results.

Krall et al. (2013) took a slightly different approach than Lippmann et al. (2013a) in an analysis of 72 U.S. cities, by focusing on those components that contribute the most (i.e., approximately 79−85%) of yearly and seasonal $PM_{2.5}$ mass. The authors developed city-specific component models and also examined associations by season (i.e., spring, summer, fall, and winter) and by region (i.e., Northeast, Southeast, southern Midwest, northern Midwest, Southwest, and Northwest). Krall et al. (2013) observed the strongest associations for OCM, EC, Si, and Na^+, but overall reported no evidence that any of these components is more strongly associated with mortality than $PM_{2.5}$ mass (Figure 11-15). Additionally, the authors reported no evidence that individual component associations varied by season or region.

In addition to the U.S. based multicity studies detailed above, Basagaña et al. (2015) examined the association between short-term exposure to $PM_{2.5}$ components and mortality in five cities in southern Europe as part of the MED-PARTICLES project. The components examined were selected a priori and based on their detectability in each of the five cities as well as evidence from the literature linking each of the $PM_{2.5}$ components with health. In single-component models the authors observed the strongest associations with SiO_2 and total (nonaccidental) mortality; SiO_2, Mg, and Mn and cardiovascular mortality; and SO_4^{2-}, K, and Mn and respiratory mortality.



Source: Permission pending, Krall et al. (2013).

Figure 11-15 Percent increase in mortality for $PM_{2.5}$ and $PM_{2.5}$ components for an interquartile range (IQR) increase in concentrations at lag 1 across 72 U.S. cities.

U.S.-based single-city studies conducted in locations across the country provide additional information that can aid in the interpretation of $PM_{2.5}$ component results from multicity studies. In a study conducted in New York City, NY focusing on cardiovascular mortality, Ito et al. (2011) examined associations with $PM_{2.5}$ components that were selected for inclusion in the study "based on past source apportionment studies in New York City as well as recent health effects studies". In all-year analyses, when focusing on those components that are the largest contributors to $PM_{2.5}$ mass, the authors observed the strongest associations for EC, OC, and SO_4^{2-} at lag 1. These results persisted in the warm season, but in the cold season the association remained the strongest for EC, and although the positive magnitude of the association and precision were reduced for OC and SO_4^{2-}. Among the other components examined, associations were observed in all-year and seasonal analyses for Br and Na^+, whereas for Se there was evidence of an association in all-year and warm season analyses at lag 1, but not in the cold season. For Ni, V, and Zn, there was no evidence of an association in all-year or warm season analyses, but lag 3 in the cold season, which is consistent with the burning of residual oil in NYC (see Section 11.1.11.2).

Although Ito et al. (2011) examined seasonal differences in $PM_{2.5}$ component associations, the authors were limited by the one-in-three sampling schedule of the monitors. Examining the associations between total, cardiovascular and respiratory mortality and $PM_{2.5}$ components, Zhou et al. (2011) was able to more rigorously examine potential differences in seasonal associations (i.e., examine both single and multiday lags) compared to Ito et al. (2011) due to the availability of daily $PM_{2.5}$ component data.

Similar to other component studies detailed in this section, the authors selected $PM_{2.5}$ components for inclusion in the study based on evidence from the toxicological literature. When examining the seasonal pattern of associations using a distributed lag model for 0−2 days, there was a clear difference in potential sources of $PM_{2.5}$ based on the strongest $PM_{2.5}$ associations with total and cause-specific mortality occurring in the warm season for Detroit and the cold season for Seattle (see Section 11.1.11.2). In both locations, mean 24-hour average $PM_{2.5}$ concentrations were near of below15 $\mu g/m^3$ for the duration of the study (Detroit = 15.1 $\mu g/m^3$; Seattle = 9.7 $\mu g/m^3$). The seasonal pattern in $PM_{2.5}$ mass associations observed in both cities were further reflected when examining $PM_{2.5}$ component associations. In Detroit in the warm season for total (nonaccidental) mortality there was evidence of positive associations for S and EC, with a strong negative association for Si. This pattern of associations was similar for cardiovascular mortality, although the confidence intervals for each component were larger. Wider confidence intervals were also observed for respiratory mortality, with positive associations only for Ni and S. For Seattle in the cold season, the component associations observed for total (nonaccidental) mortality and cardiovascular mortality were similar with positive associations observed for Al, Fe, K, Ni, S, Si, Zn, and EC. Additionally, there was some evidence of a positive association between only cardiovascular mortality and V. When examining respiratory mortality in Seattle there was no evidence of a positive association with any $PM_{2.5}$ components. In both the Detroit and Seattle data sets, Zhou et al. (2011) conducted sensitivity analyses focusing on model specification and did not observe any evidence that $PM_{2.5}$ component-mortality associations changed when increasing the degrees of freedom to control for temporal trends or when using alternative temperature variables, which is similar to what has been observed when examining $PM_{2.5}$ mass (see Section 11.1.5.1).

Kim et al. (2015) also used daily $PM_{2.5}$ component data in a study in Denver, CO that examined total (nonaccidental), cardiovascular, and respiratory mortality. However, unlike a number of the studies focusing on $PM_{2.5}$ components the authors only focused on a few of the main contributors to $PM_{2.5}$ mass (i.e., EC, OC, SO_4^{2-}, and NO_3^-). Across mortality outcomes, the strongest associations were observed for total (nonaccidental) mortality for the 0−3 distributed lag model results for EC and OC, with less evidence of an association for SO_4^{2-} and NO_3^-. For cardiovascular mortality there was only evidence for a positive association with OC and lag 1; whereas for respiratory mortality there was evidence of a positive association at lag 3 for both EC and OC. Similar to Zhou et al. (2011) in sensitivity analyses focusing on model specification the authors did not observe that $PM_{2.5}$ component-mortality associations changed when increasing the degrees of freedom to control for temporal trends or when using alternative temperature variables.

As detailed above, the majority of $PM_{2.5}$ component studies have examined whether one or a combination of components are driving the $PM_{2.5}$ mass associations, but Liu and Zhang (2015) examined whether associations with $PM_{2.5}$ mass and components have changed over time. The design of this study is like that of Dominici et al. (2007) which also attempted to examine whether PM-mortality risks have changed over time, but on a national scale. As detailed in the 2009 PM ISA, "a flaw in the use of the time-series study design for this type of analysis is that it adjusts for long-term trends, and therefore, does

not estimate the change in mortality in response to the gradual change in [PM]." As a result, the focus is on the $PM_{2.5}$ mass and component results detailed for the entire study period along with the seasonal analyses. Similar to previous studies, the components examined were selected a priori and based on evidence from the epidemiologic literature as well as a local source apportionment study (Liu and Zhang, 2015). When focusing on associations at lag 1, $PM_{2.5}$ mass had the strongest association, with evidence of a positive association for a number of individual components (Figure 11-13). When conducting seasonal analyses, the strongest associations tended to be observed during the winter, specifically for NH_4^+, Br, Cr, Mn, Ni, SO_4^{2-}, NO_3^-, V, EC, and OC. The seasonal component results are consistent with the $PM_{2.5}$ results where the association with the largest magnitude was also observed to be in the winter.

Additional $PM_{2.5}$ Component Analyses

The majority of $PM_{2.5}$ component studies conducted to date have focused almost exclusively on examining single-component models. However, a main limitation of single component models is their inability to account for the potential confounding effects of $PM_{2.5}$ mass or other $PM_{2.5}$ components. As detailed in Mostofsky et al. (2012) there are a number of alternative statistical approaches that can be used, each with their own strengths and limitations. A few of the studies detailed above that focused on single pollutant models also examined alternative models to further inform the $PM_{2.5}$ component-mortality relationship.

Lippmann et al. (2013a) used a traditional two-pollutant (i.e., copollutant) model in an attempt to examine whether $PM_{2.5}$ mass confounds the component associations observed for a subset of the components examined. In an all-year analysis, component results were robust to inclusion of $PM_{2.5}$ in the model for OC, V, Si, K, and Cu, with evidence of potential confounding for EC and SO_4^{2-}, but these two components contribute a large percentage to $PM_{2.5}$ mass and are often found to be highly correlated. In seasonal analyses, all components were robust to the inclusion of $PM_{2.5}$ in the model in the warm season, with some evidence of attenuation of the component association in the cold season for V, Si, K, and Cu, while SO_4^{2-} was found to be negatively associated with mortality.

Instead of applying a traditional copollutant model to examine component associations, Basagaña et al. (2015) and Kim et al. (2015) used the component residual approach. In this approach, the residuals from the regression of $PM_{2.5}$ on each component are included in the model, which provides the effect of each individual component holding $PM_{2.5}$ constant and theoretically eliminates confounding by $PM_{2.5}$ (Mostofsky et al., 2012). As detailed in Table 11-3, Basagaña et al. (2015) reported evidence that component results were relatively robust using the component residual approach to examine associations. Similarly, Kim et al. (2015) reported that individual component associations were relatively consistent with those observed in single-component models when using the component residual approach (Figure 11-13).

Summary

Since the completion of the 2009 PM ISA there has been a growing body of single and multicity epidemiologic studies that examined the association between short-term exposures to $PM_{2.5}$ components and mortality. As depicted in Figure 11-13, $PM_{2.5}$ component studies reported positive associations with multiple PM components at various lags using both single component models as well as alternative models. Studies have demonstrated positive associations with a number of $PM_{2.5}$ components, but across studies there is a varying degree to which components have been found to be positively associated with mortality. In comparison, there is evidence of consistent positive associations between $PM_{2.5}$ mass and mortality across all studies examined (Figure 11-14). As demonstrated in some studies the different pattern of component associations is reflective of the different sources of $PM_{2.5}$ across cities. Collectively, recent studies further support the conclusions of the 2009 PM ISA, indicating that many $PM_{2.5}$ components are associated with mortality, but no one component is more strongly associated with mortality than $PM_{2.5}$ mass.

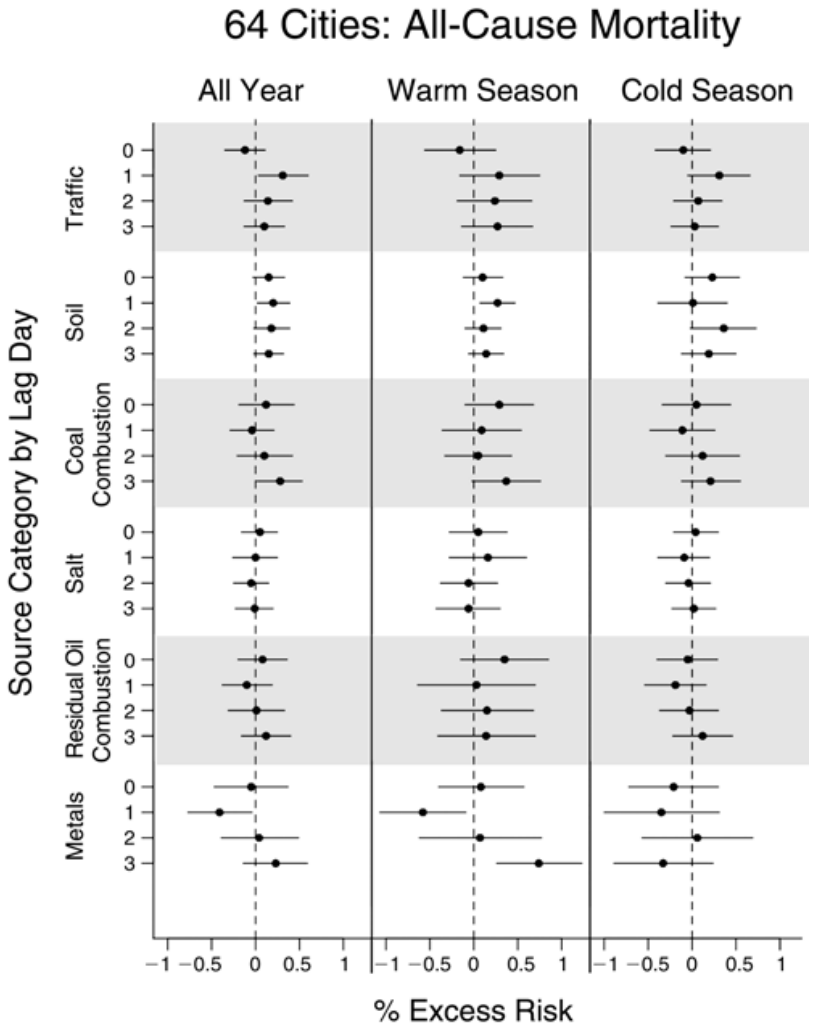
11.1.11.2 Sources

A few studies evaluated in the 2009 PM ISA conducted source apportionment analyses to examine whether specific sources of $PM_{2.5}$ are more strongly associated with mortality. These studies generally found that the most consistent associations were for $PM_{2.5}$ from combustion-related activities, which supports the results from studies evaluated in the 2004 PM AQCD (U.S. EPA, 2004). Recent studies focus primarily on examining individual $PM_{2.5}$ component associations, but also often link the components evaluated to specific $PM_{2.5}$ sources a priori. As a result, most recent studies do not rely on formal mathematical approaches, such as source apportionment, to identify sources in the context of examining the relationship between source exposures and daily mortality. As detailed in the Preface, the evaluation of associations between health effects and sources is limited to those studies that use mathematical approaches and do not identify sources a priori.

Within the NPACT study Lippmann et al. (2013a) conducted a factor analysis to identify $PM_{2.5}$ sources. The factor analysis was conducted at the national level using both $PM_{2.5}$ components along with gaseous pollutant data from all 64 U.S. cities to identify source categories: traffic (EC, OC, and NO_2), soil (Al, Si, and Ti), coal combustion (As, Se, and SO_2), residual oil combustion (Ni and V), salt (Na and Cl), and metals (Fe, Mn, and Zn). These source categories were then applied to each of the 64 U.S. cities to see which sources were found in each city. Because the source categories were based on a mathematical model they may not be representative of the sources in each city, and the interpretation of a source category on a city-to-city basis may be different (Lippmann et al., 2013a).

When examining source categories in each city, the number of cities that were found to encompass each of the source categories varied. Across cities, the sources identified in each varied with 63 cities having a traffic and soil source, 46 cities having a coal combustion source, 42 cities having a salt

source, 29 cities having a residual oil combustion source, and 16 cities having a metals source. The results of the source analysis using the individual city results and the national results were found to be relatively similar. As depicted in Figure 11-16, in all-year and seasonal analyses multiple sources were found to be associated with mortality at a number of lags.



Source: Permission pending, Lippmann et al. (2013a).

Figure 11-16 Percent increase in total (nonaccidental) mortality for individual cities within the 64 U.S. cities examined in the National Particle Component Toxicity (NPACT) study for a median interquartile range (IQR) increase in factor scores for the cities combined.

In addition to Lippmann et al. (2013a) where specific sources where defined using statistical approaches, Kollanus et al. (2016) examined whether there was evidence of differential effects on days impacted by vegetative fires (i.e., smoke days) compared to regular (i.e., nonsmoke) days in Helsinki, Finland. The authors predicted surface smoke concentrations at 1°×1° grid cells, and defined smoke days using three approaches: (1) 24-hour average $PM_{2.5}$ concentrations at urban background site ≥25 μg/m^3; (2) 24-hour average $PM_{2.5}$ or PM_{10} concentration at regional background site ≥20 μg/m^3; or (3) the smoke prediction model indicated abundant or some smoke due to long-range transport from vegetative fires. On smoke days, mean $PM_{2.5}$ concentrations were more than three times higher than nonsmoke says (i.e., 30 μg/m^3 vs. 8.6 μg/m^3); however, only 72 days during the 10-year study period were classified as smoke days. When comparing smoke to nonsmoke days, the percent increase in nonaccidental mortality was almost double on smoke days (i.e., lag 2: 2.5−2.7% for all ages and ≥65 years, respectively), but dramatically larger when examining cardiovascular mortality where there was no evidence of an association for nonsmoke days (i.e., 8.0−13.8% across individual lags of 0 and 3 day for all ages and ≥65 years).

In summary, when examining sources of $PM_{2.5}$, the results of the limited number of recent studies further support studies evaluated in the 2004 PM AQCD and 2009 PM ISA, demonstrating that combustion-related sources are often found to be associated with mortality. Collectively, the results of recent studies that examined the association between $PM_{2.5}$ sources and mortality are consistent with the conclusions of the 2009 PM ISA.

11.1.12 Summary and Causality Determination

Recent multicity studies evaluated since the completion of the 2009 PM ISA continue to provide evidence of primarily positive associations between short-term $PM_{2.5}$ exposures and total (nonaccidental) mortality from studies conducted mostly in urban areas using traditional exposure assignment approaches (i.e., average of all available monitors) as well as studies with a larger spatial coverage (i.e., urban and rural areas) employing new methods using all available $PM_{2.5}$ data (i.e., combination of monitoring, satellite and LUR). Additionally, the evidence from recent studies further substantiates the relationship between short-term $PM_{2.5}$ exposure and mortality by providing additional information on potential copollutant confounding; effect modification (e.g., stressors, pollutants, season); geographic heterogeneity in associations; and the shape of the C-R relationship, which collectively reaffirms that a causal relationship exists between short-term $PM_{2.5}$ exposure and mortality. The body of evidence for total mortality is supported by generally consistent positive associations with cardiovascular and respiratory mortality. Although there is coherence of effects across the scientific disciplines (i.e., animal toxicological, controlled human exposure studies, and epidemiologic) and biological plausibility for $PM_{2.5}$-related cardiovascular (Chapter 6) and respiratory (Chapter 5) morbidity, there is strong evidence indicating biological plausibility for $PM_{2.5}$-related cardiovascular mortality with more limited evidence for respiratory mortality. This section describes the evaluation of evidence for total (nonaccidental)

mortality, with respect to the causality determination for short-term exposures to $PM_{2.5}$ using the framework described in Table II of the Preamble to the ISAs (U.S. EPA, 2015b). The key evidence, as it relates to the causal framework, is summarized in Table 11-4.

Table 11-4 Summary of evidence for a causal relationship between short-term $PM_{2.5}$ exposure and total mortality.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Consistent epidemiologic evidence from multiple, high quality studies at relevant $PM_{2.5}$ concentrations	Increases in mortality in multicity studies conducted in the U.S., Canada, Europe, and Asia. Total mortality associations, further supported by increases in cardiovascular and respiratory mortality in multicity studies conducted in the U.S., Canada, Europe, and Asia.	Section 11.1.2 Figure 11-1 Figure 11-2 Section 5.1.9 Section 6.1.9	Mean 24-h avg: U.S. and Canada: 4.37–17.97 Europe: 13–27.7[d] Asia: 11.8–69.9 Table 11-1
Epidemiologic evidence from copollutant models provides some support for an independent $PM_{2.5}$ association	The magnitude of $PM_{2.5}$ associations remain positive, but in some cases are reduced with larger confidence intervals in copollutant models with gaseous pollutants and $PM_{10-2.5}$, supporting the limited evidence from the 2009 PM ISA. Further support from copollutant analyses indicating positive associations for cardiovascular and respiratory mortality. Recent studies that examined potential copollutant confounding are limited to studies conducted in Europe and Asia. When reported, correlations with gaseous copollutants were primarily in the low ($r < 0.4$) to moderate ($r \geq 0.4$ or <0.8) range.	Section 11.1.4 Figure 11-3 Section 5.1.10.1 Section 6.1.14.1	
Epidemiologic evidence supports a linear, no-threshold concentration-response (C-R) relationship	Recent multicity studies conducted in the U.S. and Europe provide direct evidence of a linear, no-threshold C-R relationship at lower $PM_{2.5}$ concentrations with initial evidence of a steeper slope, but extensive systematic evaluations of alternatives to linearity have not been conducted.	Section 11.1.10 Shi et al. (2015) Lee et al. (2015c) Di et al. (2017a)	

Table 11-4 (Continued): Summary of evidence indicating that a causal relationship exists between short-term $PM_{2.5}$ exposure and total mortality.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Biological plausibility from cardiovascular morbidity evidence	Strong evidence for coherence of effects across scientific disciplines and biological plausibility for a range of cardiovascular effects in response to short-term $PM_{2.5}$ exposure, specifically for ischemic events and heart failure, which is supported by experimental evidence and epidemiologic studies examining hospital admissions and ED visits. The collective body of cardiovascular morbidity evidence provides biological plausibility for a relationship between short-term $PM_{2.5}$ exposure and cardiovascular mortality, which comprises ~33% of total mortality.[e]	Section 6.1.16 Table 6-33	
Limited biological plausibility from respiratory morbidity evidence	Limited evidence for coherence of effects across scientific disciplines and biological plausibility, with the strongest evidence for exacerbations of COPD and asthma. The collective body of respiratory morbidity evidence provides limited biological plausibility for a relationship between short-term $PM_{2.5}$ exposure and respiratory mortality, which comprises ~9% of total mortality.[e]	Section 5.1.12 Table 5-18	
Uncertainty regarding geographic heterogeneity in $PM_{2.5}$ associations	Multicity U.S. studies demonstrate city-to-city and regional heterogeneity in $PM_{2.5}$-mortality associations. Evidence supports that a combination of factors including composition and exposure factors may contribute to the observed heterogeneity.	Section 11.1.6.3

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

[d]Median concentration from Samoli et al. (2013).

[e]Statistics taken from NHLBI (2017).

Collectively, the evidence from recent multicity studies of short-term $PM_{2.5}$ exposures and mortality primarily demonstrates positive associations with total (nonaccidental) mortality, with increases ranging from 0.19% (Lippmann et al., 2013a) to 2.80% (Kloog et al., 2013) at lags of 0 to 1 days in single-pollutant models. These results are further supported by initial studies employing causal inference and quasi-experimental statistical approaches (Section 11.1.2.1). Whereas most studies rely on assigning exposure using data from ambient monitors, some recent studies have also employed approaches that use

all available $PM_{2.5}$ data (i.e., monitor, satellite, and LUR) allowing for the inclusion of less urban and rural locations in analyses (Lee et al., 2015c; Shi et al., 2015; Kloog et al., 2013). Recent studies expand the assessment of potential copollutant confounding on the $PM_{2.5}$-mortality relationship, and provide additional evidence supporting that $PM_{2.5}$ associations remain positive and relatively unchanged in copollutant models with both gaseous pollutants and $PM_{10-2.5}$, but this assessment is limited to multicity studies conducted in Europe and Asia where mean 24-hour average $PM_{2.5}$ concentrations are higher (Table 11-4). However, the low ($r < 0.4$) to moderate correlations ($r = 0.4 < 0.7$ between $PM_{2.5}$ and gaseous pollutants and $PM_{10-2.5}$ increase the confidence in $PM_{2.5}$ having an independent effect on mortality.

The positive associations for total (nonaccidental) mortality reported across the majority of studies evaluated is further supported by analyses focusing on cause-specific mortality that continue to provide evidence of generally consistent positive associations with both cardiovascular and respiratory mortality, except in the case of a multicity study conducted in Europe (Lanzinger et al., 2016). Risk estimates for cardiovascular mortality ranged from 0.09% (Lippmann et al., 2013a) to 2.32% (Lee et al., 2015c) while those for respiratory mortality ranged from 0.09% (Lee et al., 2015c) to 2.30% (Janssen et al., 2013), but overall associations tend to be larger in magnitude for respiratory mortality. For both cardiovascular and respiratory mortality there was a limited assessment of potential copollutant confounding, but for both outcomes initial evidence indicates that associations remain positive and relatively unchanged in models with gaseous pollutants and $PM_{10-2.5}$, further supporting the copollutant analyses conducted for total (nonaccidental) mortality. The strong evidence for ischemic events and heart failure as detailed in the assessment of cardiovascular morbidity (Chapter 6), provide strong biological plausibility for $PM_{2.5}$-related cardiovascular mortality, which comprises the largest percent of total mortality (i.e., ~33%) (NHLBI, 2017). Although there is evidence for exacerbations of COPD and asthma, the collective body of respiratory morbidity evidence provides limited biological plausibility for $PM_{2.5}$-related respiratory mortality (Chapter 5).

In addition to examining potential copollutant confounding, a number of studies also assessed whether statistical models adequately account for temporal trends and weather covariates. Across studies that evaluated model specification, $PM_{2.5}$-mortality associations remained positive, although in some cases were attenuated, when using different approaches to account for temporal trends or weather covariates (Section 11.1.5). Seasonal analyses continue to provide evidence that associations are larger in magnitude during warmer months, but it remains unclear if copollutants confound the associations observed. In addition to seasonal analyses, some studies also examined whether temperature modifies the $PM_{2.5}$-mortality relationship. Initial evidence indicates that the $PM_{2.5}$-mortality association may be larger in magnitude at lower and higher temperatures, but this observation has not been substantiated by studies conducted in the U.S. (Section 11.1.6.2).

At the completion of the 2009 PM ISA, one of the main uncertainties identified was the regional and city-to-city heterogeneity in $PM_{2.5}$-mortality associations observed in multicity studies. Recent studies

examined both city specific as well as regional characteristics to identify the underlying factors that contribute to this heterogeneity (Section 11.1.6.3). Analyses focusing on effect modification of the $PM_{2.5}$-mortality relationship by $PM_{2.5}$ components, regional patterns in $PM_{2.5}$ components and city-specific differences in composition and sources indicate some differences in the $PM_{2.5}$ composition and sources across cities and regions, but these differences do not fully explain the heterogeneity observed. Additional studies examined whether exposure factors play a role in explaining the heterogeneity in $PM_{2.5}$-mortality associations and found that some factors related to housing stock and commuting as well as city-specific factors (e.g., land-use, port volume, and traffic information) also explain some of the observed heterogeneity. Collectively, recent studies indicate that the heterogeneity in $PM_{2.5}$-mortality risk estimates cannot be attributed to one factor, but instead a combination of factors including, but not limited to, compositional and source differences as well as exposure differences.

A number of recent studies conducted systematic evaluations of the lag structure of associations for the $PM_{2.5}$-mortality relationship by examining either a series of single-day or multiday lags and these studies continue to support an immediate effect (i.e., lag 0 to 1 days) of short-term $PM_{2.5}$ exposures on mortality (Section 11.1.8.1). Recent studies also conducted analyses comparing the traditional 24-hour average exposure metric with a subdaily metric (i.e., 1-hour max). These initial studies provide evidence of a similar pattern of associations for both the 24-hour average and 1-hour max metric, with the association larger in magnitude for the 24-hour average metric. Additionally, some studies examined alternative exposure metrics representing size fractions smaller than $PM_{2.5}$ and reflecting NC and SC. The generally positive associations reported with mortality for these smaller PM size fractions support the larger body of $PM_{2.5}$-mortality evidence, but it is difficult to compare NC and SC metrics with the traditional mass-based metric.

Building off the initial analysis of the C-R relationship between short-term PM exposure and mortality that focused on PM_{10}, recent multicity studies conducted in the U.S. and Europe examined the shape of the C-R relationship and whether a threshold exists specifically for $PM_{2.5}$ (Section 11.1.10). These studies have used different statistical approaches and consistently demonstrated a linear relationship with no evidence of a threshold. Additionally, recent analyses conducted at lower $PM_{2.5}$ concentrations (i.e., 24-hour average $PM_{2.5}$ concentrations <30 $\mu g/m^3$) provide initial evidence indicating that $PM_{2.5}$-mortality associations persist and may be stronger (i.e., a steeper slope) at lower concentrations. However, to date, studies have not conducted extensive analyses exploring alternatives to linearity when examining the shape of the $PM_{2.5}$-mortality C-R relationship.

Overall, recent epidemiologic studies build upon and further reaffirm the conclusions of the 2009 PM ISA for total mortality. The evidence particularly from the assessment of $PM_{2.5}$-related cardiovascular morbidity, with more limited evidence from respiratory morbidity, provides biological plausibility for mortality due to short-term $PM_{2.5}$ exposures. In conclusion, the primarily positive associations observed across studies conducted in various locations is further supported by the results from copollutant analyses indicating robust associations, along with evidence from analyses of the C-R relationship. **Collectively,**

this body of evidence is sufficient to conclude that a causal relationship exists between short-term $PM_{2.5}$ exposure and total mortality.

11.2 Long-Term $PM_{2.5}$ Exposure and Total Mortality

The 2009 PM ISA reported that the evidence was "sufficient to conclude that the relationship between long-term $PM_{2.5}$ exposures and mortality is causal" (U.S. EPA, 2009).[79] Two seminal cohort studies, the American Cancer Society (ACS) and the Harvard Six Cities studies provided the strongest evidence for this conclusion (i.e., consistency across studies and among replication and reanalysis of the same cohort; study designs appropriate for causal inference), and were supported by evidence from other cohort studies conducted in North America and Europe. Evidence presented in the 2009 PM ISA was largely consistent with past studies reporting associations between long-term $PM_{2.5}$ exposure and increased risk of human mortality. Additional analyses of the Harvard Six Cities cohort demonstrated a reduction in mortality risk associated with decreases in $PM_{2.5}$ concentrations (Laden et al., 2006). Similarly, Pope et al. (2009) reported that decreases in $PM_{2.5}$ concentrations were associated with increases in life expectancy. Another new line of evidence supporting the causality determination in the 2009 PM ISA was the increased risk in death from cardiovascular disease among a cohort of post-menopausal women with no previous history of cardiovascular disease (Miller et al., 2007).

The following section provides a brief, integrated evaluation of evidence for long-term $PM_{2.5}$ exposure and mortality presented in the previous NAAQS review with evidence that is newly available for this review (see Table 11-5 for study descriptions). This section focuses on assessing the degree to which newly available studies further characterize the relationship between long-term $PM_{2.5}$ exposure and mortality, focusing on studies where long-term average $PM_{2.5}$ concentrations are less than 20 $\mu g/m^3$ across all cities or where at least half of the cities have long-term average $PM_{2.5}$ concentrations less than 20 $\mu g/m^3$ (see Preface). For example, areas of research that inform differences in the exposure window used to evaluate long-term exposures and mortality or comparisons of statistical techniques will be highlighted. Studies that address the variability in the associations observed across $PM_{2.5}$ epidemiologic studies due to exposure error and the use of different exposure assessment techniques will be emphasized. Another important consideration will be characterizing the shape of the concentration-response (C-R) relationship across the full concentration range observed in epidemiologic studies. The evidence in this section will focus on epidemiologic studies because experimental studies of long-term exposure and mortality are generally not conducted. However, this section will draw from the morbidity evidence presented for different health endpoints across the scientific disciplines (i.e., animal toxicological, epidemiologic and controlled human exposure studies) to support the associations observed for cause-specific mortality.

[79] As detailed in the Preface, risk estimates are for a 5 $\mu g/m^3$ increase in annual $PM_{2.5}$ concentrations, unless otherwise noted.

11.2.1 Biological Plausibility for Long-Term $PM_{2.5}$ Exposure and Total Mortality

The preceding chapters characterized evidence related to evaluating the biological plausibility by which long-term $PM_{2.5}$ exposure may lead to the morbidity effects that are the largest contributors to total (nonaccidental) mortality, specifically cardiovascular and respiratory morbidity and metabolic disease (Section 6.2.1, Section 5.2.1, and Section 7.2.1, respectively). This evidence is derived from animal toxicological, controlled human exposure, and epidemiologic studies. Section 6.2.1 outlines the available evidence for plausible mechanisms by which inhalation exposure to $PM_{2.5}$ could progress from initial events to endpoints relevant to the cardiovascular system and to population outcomes such as IHD, stroke and atherosclerosis. Similarly, Section 5.2.1 characterizes the available evidence by which inhalation exposure to $PM_{2.5}$ could progress from initial events to endpoints relevant to the respiratory system and to population outcomes such as exacerbation of COPD. Section 7.2.1 outlines the available evidence for plausible mechanisms by which inhalation exposure to $PM_{2.5}$ could progress from initial events (e.g., pulmonary inflammation, autonomic nervous system activation) to intermediate endpoints (e.g., insulin resistance, increased blood glucose and lipids) and result in population outcomes such as metabolic disease and diabetes. Collectively, the progression demonstrated in the available evidence for cardiovascular and respiratory morbidity and metabolic disease supports potential biological pathways by which long-term $PM_{2.5}$ exposures could result in mortality.

11.2.2 Associations between Long-Term $PM_{2.5}$ Exposure and Mortality

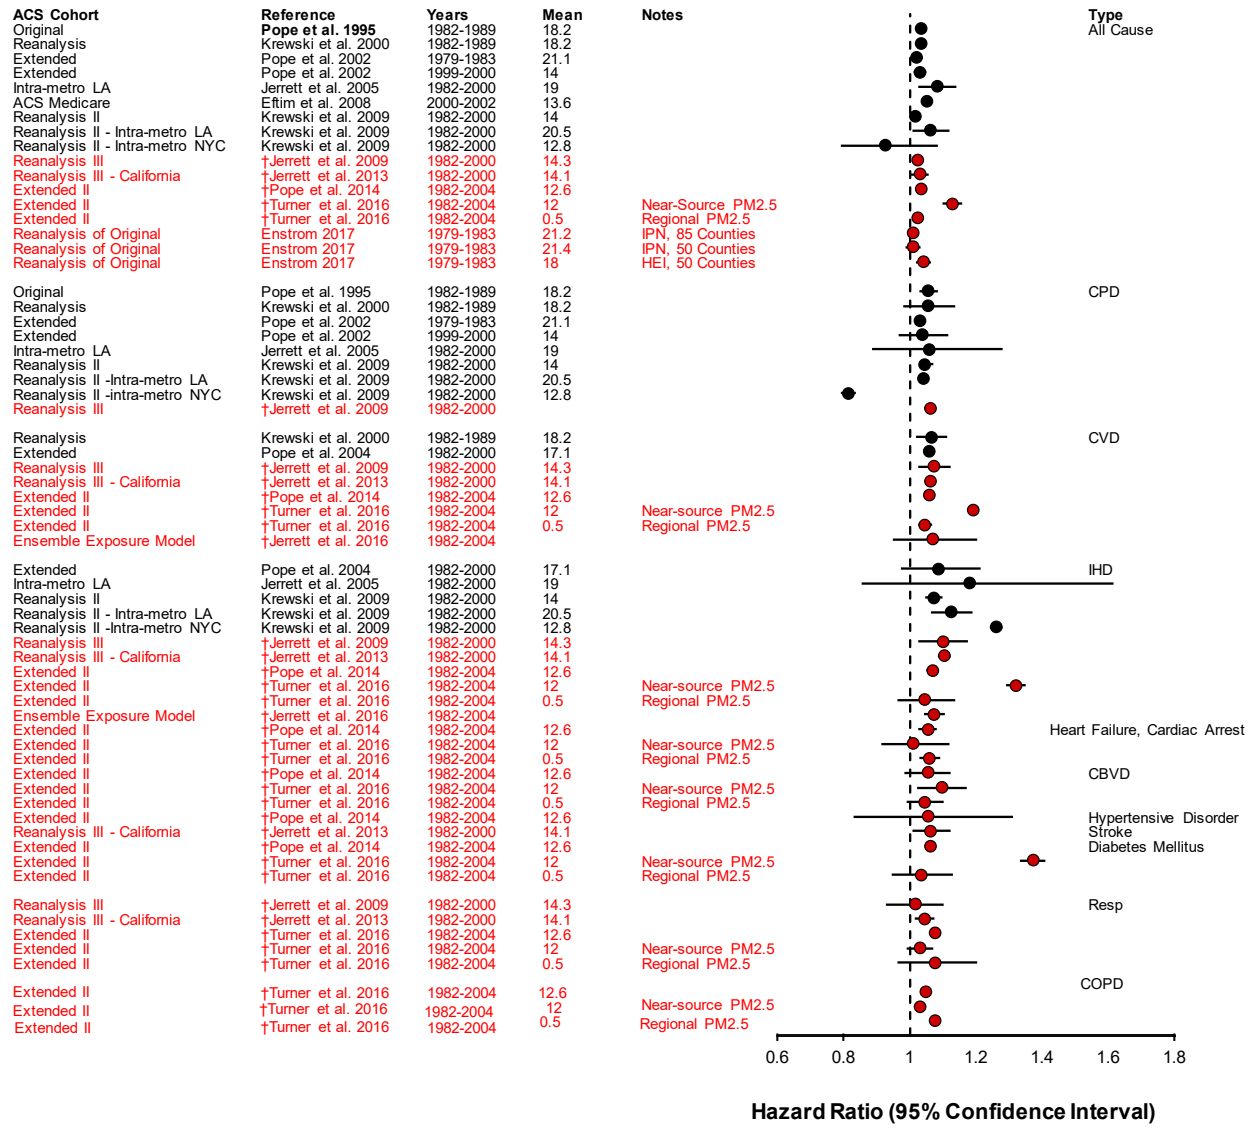
11.2.2.1 Results of American Cancer Society (ACS) and Harvard Six Cities Cohort Studies

Results from the ACS and Harvard Six Cities cohorts have provided evidence on the associations between long-term $PM_{2.5}$ exposure and mortality in the 1996 PM AQCD (U.S. EPA, 1996), the 2004 PM AQCD (U.S. EPA, 2004) and the 2009 PM ISA (U.S. EPA, 2009). Each of these cohort studies are broadly representative of the U.S. population and have undergone extensive independent replication and extended reanalysis. Numerous results from replication and reanalysis of the ACS study are summarized in Figure 11-17.

Many new analyses further evaluated the associations of long-term $PM_{2.5}$ exposures with risk of mortality based on the original ACS study (Pope et al., 1995), adding new details about deaths due to cardiovascular disease (including IHD) and respiratory disease (including COPD), and extending the follow-up period of the ACS to 22 years (1982−2004). In particular, Pope et al. (2014) and Turner et al. (2016) used the extended follow-up period of the ACS to examine the associations between long-term

$PM_{2.5}$ exposure and total (nonaccidental), cardiovascular, ischemic heart disease, heart failure and cardiac arrest, cerebrovascular disease, hypertensive disease, diabetes mellitus, respiratory disease, COPD and lung cancer. In these extended analyses, they applied a new method to assign exposure, specifically a national-level land use regression (LUR) and Bayesian Maximum Entropy (BME) prediction model (LUR-BME; see Section 3.4.5.2 for details). The results of these extended analyses were consistent with previous results from the ACS cohort for total (nonaccidental), cardiovascular, and ischemic heart disease (Figure 11-17). In addition, these extended analyses provide evidence of positive associations for causes of death that had previously not been evaluated among the ACS cohort. Positive associations were observed with heart failure and cardiac arrest, cerebrovascular disease, hypertensive disorder, diabetes mellitus, respiratory disease and COPD. A recent reanalysis of early ACS results observed a null association between county-level averages of $PM_{2.5}$ measured by the Inhalable Particle Network between 1979 and 1983 and deaths between 1982 and 1988 (HR: 1.01; 95% CI: 1.00, 1.02) (Enstrom, 2017). Inconsistencies in the results could be due to the use of 85 counties in the ACS analysis by Enstrom (2017) and 50 Metropolitan Statistical Areas in the original ACS analysis (Pope et al., 1995).

Another benefit of the multiple reanalysis and extended analyses of the ACS cohort is the ability to compare the results of using different techniques to assign long-term $PM_{2.5}$ exposures (e.g., monitors, models, satellite-based methods, or combinations of multiple techniques). The original analysis of the ACS cohort (Pope et al., 1995) and several extended analyses [e.g., (Jerrett et al., 2009)] used area-wide averages of $PM_{2.5}$ concentrations measured by fixed-site monitors to assign exposure. As previously mentioned, the most recent extended analyses relied on LUR-BME models (Turner et al., 2016; Pope et al., 2014). In addition, Jerrett et al. (2013) used a LUR model to assign exposure to the subset of the ACS cohort residing in California while evaluating the association between long-term $PM_{2.5}$ exposure and total (nonaccidental) and cause-specific mortality. Turner et al. (2017) evaluated the interaction between ambient $PM_{2.5}$ exposure and smoking in the entire ACS cohort. As demonstrated in Figure 11-17, the results of all of these studies are consistent in the direction and magnitude of effect, providing evidence that these associations are not artifacts related to the type of exposure assessment used, and that they are robust to different kinds of exposure measurement error that may be associated with different exposure assessment techniques (Section 3.4.5.2).



CPD = cardiopulmonary disease; CVD = cardiovascular disease; IHD = ischemic heart disease; CBVD = cerebrovascular disease; Resp = respiratory disease; COPD = chronic obstructive pulmonary disease; IPN = inhalable particle network; HEI = $PM_{2.5}$ data from Health Effects Institute reanalysis.

Note: †Studies published since the 2009 PM ISA. Circles represent point estimates; horizontal lines represent 95% confidence intervals for $PM_{2.5}$. Black text and circles represent evidence included in the 2009 PM ISA; red text and circles represent recent evidence not considered in previous ISAs or AQCDs. Mean concentrations in $\mu g/m^3$. Hazard Ratios are standardized to a 5-$\mu g/m^3$ increase in $PM_{2.5}$ concentrations. Studies are nationwide unless otherwise noted.

Corresponding quantitative results are reported in Supplemental Table S11-4 (U.S. EPA, 2018b).

Figure 11-17 Associations between long-term exposure to PM2.5 and total (nonaccidental) mortality in the American Cancer Society (ACS) cohort.

In addition to the reanalysis of the ACS cohort, Lepeule et al. (2012) reported the results of an extended analysis of the Harvard Six Cities cohort, extending the follow-up period to include deaths between 1974 and 2009. The authors included results for the association between long-term $PM_{2.5}$

exposure and total (nonaccidental), cardiovascular, COPD and lung cancer mortality. The results for total (nonaccidental), cardiovascular, and lung cancer mortality were consistent with previous analyses of the Harvard Six Cities cohort. This was the first time that COPD mortality was evaluated among the Harvard Six Cities cohort; the relative risk was positive with wide confidence intervals due to the smaller number of COPD deaths compared to deaths from other causes.

Overall, analyses of the ACS and the Harvard Six Cities cohorts continue to provide strong support for the causal relationship between long-term $PM_{2.5}$ exposure and mortality. Results from recent reanalysis and extended analyses of data from the ACS cohort are consistent with the previous results from this cohort, and have also added more information about some causes of mortality that was not available in the 2009 PM ISA. These studies also contribute to the improved characterization of the relationship between $PM_{2.5}$ and mortality, informing the shape of the C-R relationship (Section 11.2.4), role of copollutants evaluated in copollutant models (Section 11.2.3), impact of different exposure assessment techniques (Section 11.2.5.1), and evaluation of different windows of exposure (Section 11.2.5.3). Results from the ACS and Harvard Six Cities Cohorts that inform these aspects of the relationship will be integrated and synthesized with the results from other cohort studies in the following sections.

11.2.2.2 Results of other North American Cohort Studies

A number of cohort studies have recently been conducted in the U.S. and Canada and are consistent with the results observed in the ACS and Harvard Six Cities cohort studies, while providing additional information about the relationship between long-term $PM_{2.5}$ exposure and mortality among different subpopulations (e.g., women, teachers, nurses, truck drivers), in locations with generally low annual $PM_{2.5}$ concentrations, and using different methods for assigning exposure to $PM_{2.5}$. Results from studies of total (nonaccidental) mortality are summarized in Figure 11-18, while the results for all cardiovascular and all respiratory mortality are summarized in Figure 11-19. More specific results on cause-specific mortality can be found in Section 6.3.9 and Section 5.2.10.

Figure 11-19 Associations between long-term exposure to $PM_{2.5}$ and all cardiovascular disease (CVD) and all respiratory mortality in recent North American cohorts.

A number of recent cohort studies conducted in the U.S. and Canada have examined the relationship between long-term $PM_{2.5}$ exposure and mortality using innovative and novel exposure assessment and statistical techniques in areas where annual average $PM_{2.5}$ concentrations are relatively low (i.e., less than 12 μg/m^3). In the U.S., Kloog et al. (2013) described a novel method of estimating temporally and spatially resolved $PM_{2.5}$ concentrations by combining results of a LUR model with daily satellite-based observations of aerosol optical depth (AOD) (see Section 3.3.3 for details). The authors

then assigned exposure based on residence at time of death for all deaths in Massachusetts, and the association between long-term $PM_{2.5}$ exposure and cardiovascular and respiratory mortality (combined) was estimated using a relative incidence analysis with a 365-day moving average of estimated $PM_{2.5}$ concentration, similar to statistical analyses of short-term exposure often used in time-series studies. Kloog et al. (2013) observed a positive association in the 365-day moving average of $PM_{2.5}$ and cardiovascular and respiratory mortality (RR: 1.26, 95% CI: 1.22, 1.34). Building on the innovative exposure assessment and statistical techniques introduced by Kloog et al. (2013), Shi et al. (2015) expanded the exposure assessment to include all of New England and used a model output that refined the spatial resolution to 1 × 1 km grid cells (see Section 3.4.5.2 for discussion of effect of spatial resolution risk estimates). These exposure data were linked to a population-based Medicare cohort and the authors observed a relative risk of 1.04 (95% CI: 1.01, 1.06) for the 365-day moving average of $PM_{2.5}$ and total (nonaccidental) mortality. This association persisted when the analysis was restricted to those with annual exposures <10 $\mu g/m^3$ (RR: 1.05, 95% CI: 1.00, 1.09 for the 365-day moving average of $PM_{2.5}$). Finally, these authors applied the refined spatial resolution (i.e., 1 × 1 km grid cells) to all Medicare beneficiaries in the continental U.S. between 2000 and 2012 (Di et al., 2017c). In an open cohort of over 60 million people, 460 million person-years of follow-up, and 22 million deaths, (Di et al., 2017c) observed an HR of 1.041 (95% CI: 1.039, 1.042) for the relationship between $PM_{2.5}$ and all-cause mortality. This association was robust in copollutant models with O_3 and when the nearest monitor was used to assign exposure. When restricting the analysis to locations for which the annual $PM_{2.5}$ concentration was <12 $\mu g/m^3$, the authors observed a stronger relationship (HR: 1.066; 95% CI: 1.063, 1.068).

Additional cohort studies looked at the relationship between long-term $PM_{2.5}$ exposure and mortality among older adults across a larger spatial extent, using more traditional exposure assessment and statistical techniques. Kioumourtzoglou et al. (2016) also used the Medicare cohort, but expanded from New England to include Medicare deaths in 207 cities across the U.S. from 2000–2010. These authors used fixed-site monitor data to calculate city-specific annual and two-year average $PM_{2.5}$ concentrations. Using a Cox proportional hazard statistical model, Kioumourtzoglou et al. (2016) observed a 9% increase in the risk of total (nonaccidental) mortality (HR: 1.09, 95% CI: 1.05, 1.13). Wang et al. (2017b) used a similar exposure assessment protocol to examine mortality in seven southeastern states. These exposure data were linked to a population-based Medicare cohort and the authors observed a hazard ratio of 1.11 (95% CI: 1.10, 1.11) for the annual average of $PM_{2.5}$ and total (nonaccidental) mortality. This association was stronger when the analyses were restricted to those with annual exposures <12 $\mu g/m^3$ (RR: 1.18, 95% CI: 1.16, 1.19). In another nationwide cohort of older Americans, Thurston et al. (2015) used census-tract estimates of monthly $PM_{2.5}$ concentration from a LUR model to assign annual mean concentrations to participants in the NIH-AARP cohort study that died between 2000 and 2009. The authors observed positive associations with total (nonaccidental), CVD and respiratory mortality, with the largest magnitude of effect observed with CVD mortality.

A recent series of studies conducted in Canada linked census data with data from the Canadian Mortality Database to create the Canadian Census Health Environment Cohort (CanCHEC). The

CanCHEC cohort included adults (≥25 years) who died between 1991 and 2001. Mean annual concentrations of $PM_{2.5}$ were calculated from fixed-site monitors in 11 cities and assigned to 43% of the cohort. In addition to using fixed-site monitors to assign exposure, exposure was also assigned using $PM_{2.5}$ predictions from satellite-based observations (with a spatial resolution of 10 × 10 km). Crouse et al. (2012) developed Cox proportional hazards models to evaluate the relationship between long-term $PM_{2.5}$ exposure and total (nonaccidental) and CVD (including IHD, CBVD, and circulatory) mortality. The authors observed positive associations between total (nonaccidental) and CVD mortality and long-term $PM_{2.5}$ exposure, with similar estimates for satellite-based observations of AOD and fixed-site monitor concentrations. The strongest association was for IHD mortality (HR: 1.31, 95% CI: 1.27, 1.35) and the weakest was for cerebrovascular mortality (HR: 1.04; 95% CI: 0.99, 1.10) (see Figure 6-19).

Using the same CanCHEC cohort and methods, Brook et al. (2013) evaluated the association between long-term exposure to $PM_{2.5}$ and mortality due to diabetes, and observed a positive association similar in magnitude to the one observed for IHD mortality in the previous study (HR: 1.23; 95% CI: 1.18, 1.28). Similarly, Chen et al. (2016) limited their analyses to cohort participants residing in Ontario who had experienced an acute myocardial infarction, and observed positive associations with total (nonaccidental), CVD, and IHD deaths, as well as deaths due to subsequent acute myocardial infarctions (range of HRs: 1.10−1.28). Crouse et al. (2015) extended the follow-up period to include five additional years (1991−2006) and evaluated several additional mortality causes, but otherwise used the same methods as those in Crouse et al. (2012). Positive associations were observed for total (nonaccidental) and cardiovascular mortality, with the strongest association observed between long-term exposure to $PM_{2.5}$ and mortality due to diabetes (HR: 1.15, 95% CI; 1.11, 1.19), followed by IHD (HR: 1.09; 95% CI: 1.07, 1.10). The associations for cerebrovascular, respiratory and COPD mortality were just below the null. The general pattern and magnitude of these associations were generally unchanged in cumulative risk models that include O_3 and/or NO_2. Weichenthal et al. (2016) evaluated the subset of the CanCHEC cohort living within 5 km of a fixed-site monitor (n = 193,300) for associations between long-term $PM_{2.5}$ exposure and mortality. They assigned the average (1998−2009) $PM_{2.5}$ concentration to each of the participants living within 5 km of each of 30 fixed-site monitors. In additional analyses, these authors observed positive associations between $PM_{2.5}$ exposure and total (nonaccidental) (HR: 1.05, 95% CI: 1.03, 1.09) and respiratory mortality (HR: 1.08, 95% CI: 0.96, 1.21), but the results for cardio-metabolic and IHD mortality were closer to the null value.

Pinault et al. (2016) linked a subset of participants from the CanCHEC cohort to the Canadian Community Health Survey, which allowed them to include an expanded set of individual-level covariates in their analyses. Among the nearly 300,000 participants included the study, the authors observed positive associations with total (nonaccidental), circulatory, and respiratory mortality similar in magnitude to those observed in the larger cohort (Crouse et al., 2012). In addition, Pinault et al. (2016) was able to make use of the individual-level covariate data to examine effect measure modification by age, sex, smoking, alcohol consumption, obesity, and fruit/vegetable consumption. In an attempt to validate the results observed in the CanCHEC cohort, Villeneuve et al. (2015) examined the association of long-term $PM_{2.5}$

exposure and mortality in a cohort of Canadian women originally enrolled in the Canadian National Breast Screening Study (CNBSS). Using similar exposure methods that relied on satellite-based estimates linked with the centroid of each six-digit postal code, Villeneuve et al. (2015) observed positive associations, similar in magnitude to those observed in previous Canadian cohorts, for total (HR: 1.06; 95% CI: 1.02, 1.10) and cardiovascular mortality (HR: 1.16; 95% CI: 1.07, 1.26), though they did not observe a positive association with respiratory mortality.

Several recent U.S. cohort studies examined the association between long-term $PM_{2.5}$ exposure and mortality in occupational cohorts. The California Teachers Study (Lipsett et al., 2011; Ostro et al., 2010) examined the association between $PM_{2.5}$ measures at fixed-site monitors and mortality among current and former female public school teachers. The authors observed positive associations between long-term $PM_{2.5}$ exposure and IHD, cerebrovascular, cardiopulmonary, and respiratory mortality, with the strongest association observed with IHD (HR: 1.70; 95% CI: 1.51, 1.91). Analyses restricted to post-menopausal women yielded results similar to those for all subjects. In a reanalysis of the cohort with refined exposure assessment, Ostro et al. (2015) used a chemical transport model to predict $PM_{2.5}$ concentrations with a 4 km spatial resolution, observing a pattern of results similar to those in the original analyses, although the magnitude of the risk estimates was smaller. Puett et al. (2009) examined the association between long-term $PM_{2.5}$ exposure and total (nonaccidental) mortality among a cohort of female nurses in the Nurses' Health Study from 13 states in the northeast and Midwest from 1992 through 2002. The authors observed positive associations with total (nonaccidental) and CHD mortality, with the strongest association observed for fatal CHD events (HR: 1.42, 95% CI: 1.03-1.94). Hart et al. (2015) expanded the Nurses' Health Study to the full nationwide cohort and extended the years of follow-up through 2006. In the updated cohort, the average $PM_{2.5}$ exposure over the previous 12 months was 12.0 $\mu g/m^3$. The results for total (nonaccidental) mortality were similar in the nationwide cohort for the extended follow-up period compared to the original results from the earlier follow-up period and more limited (i.e., smaller) spatial extent. The magnitude of the associations for long-term $PM_{2.5}$ exposure and cardiovascular mortality among women (Hart et al., 2015; Lipsett et al., 2011; Ostro et al., 2010; Puett et al., 2009) was higher than those observed in many of the other North American cohorts of men or men and women combined, but similar to that observed by Miller et al. (2007), who also evaluated fatal CHD events among a cohort of women. Using a design similar to that of the Nurses' Health Study, Puett et al. (2011) investigated the effect of long-term $PM_{2.5}$ exposure and mortality among men enrolled in the Health Professionals Follow-up Study cohort. Near null associations were observed for both total (nonaccidental) (HR: 0.94, 95% CI: 0.87, 1.02) and CHD mortality (HR: 0.97, 95% CI: 0.83, 1.13) in this cohort. In another occupational cohort, Hart et al. (2011) examined the association between residential exposure to $PM_{2.5}$ estimated from a single year of monitoring data (2000) and mortality among men in the U.S. trucking industry in the Trucking Industry Particle Study (TrIPS). Elevated risks of total (nonaccidental), lung cancer, and respiratory mortality were observed, with generally higher effects observed in subset analyses that excluded long-haul drivers.

The results of these recent U.S. and Canadian cohort studies demonstrate a consistent, positive association between long-term $PM_{2.5}$ exposure and mortality across various spatial extents, exposure assessment metrics, statistical techniques, and locations, including those where mean annual average concentrations are below ≤12 µg/m^3. Recent cohort studies in the U.S. observed increases in total mortality and mortality due to cardiovascular disease in separate cohorts of men and women. Additional cohort studies conducted in Europe observed similarly consistent, positive associations between long-term $PM_{2.5}$ exposure and mortality (see Table 11-6), and support the evidence from the U.S. and Canada. Particularly noteworthy is a study conducted in Europe that combined data from 22 existing cohort studies and evaluated the association between long-term $PM_{2.5}$ exposure and total (nonaccidental) (Beelen et al., 2014a), cardiovascular (Beelen et al., 2014b), and respiratory (Dimakopoulou et al., 2014) mortality. Including participants from 13 European countries, the authors applied a common statistical protocol to data from each of the 22 cohorts in the first stage of the analysis and combined the cohort-specific effects in a second stage. The authors observed a positive association between long-term $PM_{2.5}$ exposure and total (nonaccidental) mortality (HR: 1.07, 95% CI 1.02, 1.13) (Beelen et al., 2014a), but the associations for cardiovascular and respiratory mortality were near the null value, except for the subset of cardiovascular deaths attributable to cerebrovascular disease (HR: 1.21, 95% CI: 0.87, 1.69) (Beelen et al., 2014b).

11.2.2.3 Cardiovascular Mortality

Overall, the results of the recent U.S. and Canadian cohort studies demonstrate a consistent, positive association between long-term $PM_{2.5}$ exposure and cardiovascular mortality across various spatial extents, exposure assessment techniques, and statistical techniques, and locations, including those where mean annual average concentrations are ≤12 µg/m³. Additional cohort studies conducted in Europe observed similarly consistent, positive associations between long-term $PM_{2.5}$ exposure and cardiovascular mortality (see Table 11-6), and support the evidence from the U.S. and Canada. However, a study conducted in Europe that combined data from 22 existing cohort studies and evaluated the association between long-term $PM_{2.5}$ exposure and cardiovascular mortality (Beelen et al., 2014b) reported associations near the null value, except for the subset of cardiovascular deaths attributable to cerebrovascular disease (HR: 1.21, 95% CI: 0.87, 1.69). More detailed results of long-term $PM_{2.5}$ exposure and cardiovascular mortality are included in Section 6.3.9.

11.2.2.4 Respiratory Mortality

Overall, the results of these recent U.S. cohort studies demonstrate a generally consistent, positive association between long-term $PM_{2.5}$ exposure and respiratory mortality, though the results from the two Canadian studies are inconsistent. In addition, a study conducted in Europe that pooled data from 22 existing cohort studies and evaluated the association between long-term $PM_{2.5}$ exposure and respiratory mortality observed an association for respiratory mortality near the null value (Dimakopoulou et al., 2014). Overall, the associations for respiratory mortality were generally positive, though some inconsistencies among the results from different analyses of the same cohort provide some uncertainty in the stability of these results [Ostro et al. (2010) and Ostro et al. (2015); Crouse et al. (2015) and Pinault et al. (2016)]. Recent studies have evaluated the association between long-term $PM_{2.5}$ exposure and COPD mortality, a cause of death for which there has previously been little examination. These studies report

modest positive associations with COPD mortality and the hazard ratios are generally less precise (i.e., wider 95% confidence intervals) than those for respiratory mortality. More detailed results of long-term $PM_{2.5}$ exposure and cardiovascular mortality are included in Section 5.2.10.

11.2.2.5 Causal Inference Studies

Recently, several studies have explored the use of causal inference methods (i.e., quantitative methods and/or study design attributes) to specifically inform the causal nature of the relationship between long-term $PM_{2.5}$ exposure and mortality. A recent study employed a difference-in-difference approach as a quantitative causal inference method to examine the relationship between long-term $PM_{2.5}$ exposure and mortality in New Jersey (Wang et al., 2016). $PM_{2.5}$ concentrations were estimated at the census tract level using similar exposure assessment techniques as those used by Shi et al. (2015), discussed previously. The difference-in-difference method controls for geographical differences using dummy variables for each tract, long-term temporal trends using dummy variables for each year, and temperature, which is both correlated with $PM_{2.5}$ and can vary differentially over space and time. Wang et al. (2016) observed a positive relationship between long-term exposure to $PM_{2.5}$ and total (nonaccidental) mortality (RR: 1.08; 95% CI: 1.01, 1.15). Cox and Popken (2015) conducted an ecologic, county-level, repeated-measures analysis to evaluate the changes in $PM_{2.5}$ concentrations from 2000 to 2010 in 15 large U.S. states, and the association with age-specific mortality rates for older adults (65+ years) over the same period. The authors observed positive correlations between county-level $PM_{2.5}$ concentrations and county-level mortality rates for total (nonaccidental) and cardiovascular mortality, but not for external-cause mortality (e.g., accidents), a negative control. The authors applied several quantitative methods to inform causal inference (e.g., Granger tests), and observed effects in 6−7% of counties studied (Cox and Popken, 2015). Inference from this study is limited by a lack of individual-level data; it is an ecologic study relying on county-level mortality rates, with no control for potential confounders other than age, making it difficult to adequately interpret the results. Overall, the results of these causal inference studies contribute to the body of epidemiologic evidence that informs the causal relationship between long-term $PM_{2.5}$ exposure and total mortality. Observing consistent results for this relationship across studies using different analytic techniques (i.e., difference-in-difference approach) increases our confidence in the relationship.

11.2.2.6 Studies of Temporal Trends and Life Expectancy

A recent series of studies has added to the body of evidence on the relationship between long-term exposure to $PM_{2.5}$ and mortality by examining the temporal trends in $PM_{2.5}$ concentrations and changes in life expectancy, testing the hypothesis that decreases in $PM_{2.5}$ concentrations would be associated with increases in life expectancy. Pope et al. (2009) used air quality data in a cross-sectional analysis from 51 metropolitan areas across the U.S., beginning in the 1970s through the early 2000s, to

demonstrate that a 10 µg/m^3 decrease in long-term $PM_{2.5}$ concentration was associated with a 0.61-year increase in life expectancy. In a subsequent analysis, these authors extended the period of analysis to include 2000 to 2007 (Correia et al., 2013). While the decline in concentrations of $PM_{2.5}$ was slower for the 2000 to 2007 period, compared to the period from 1980 to 2000, a decrease in long-term $PM_{2.5}$ concentration continued to be associated with an increase in life expectancy, though the magnitude of the increase was smaller than in the previous analysis and the earlier time period (10 µg/m^3 decrease in long-term $PM_{2.5}$ concentration was associated with a 0.35-year increase in life expectancy). It is noteworthy that, by 2007, 48 of the 545 counties included in the study were not in compliance with the NAAQS (at that time, the annual standard was 15 µg/m^3). The mean concentration across all counties was 13.2 µg/m^3 in 2000, and decreased to 11.6 µg/m^3 by 2007. Using a doubly robust additive hazards model, Wang et al. (2017a) calculated that a 1 µg/m^3 decrease in the annual concentration of $PM_{2.5}$ would prevent about 5,400 premature deaths among the 13.1 million Medicare beneficiaries in seven southeastern states analyzed in Wang et al. (2017b). In an analysis conducted in Spain, de Keijzer et al. (2016) focused on the years of life lost associated with an increase in $PM_{2.5}$ rather than the life expectancy gain associated with a decrease in $PM_{2.5}$. They observed 0.64 (95% CI 0.59, 0.70) years of life lost for every 2 µg/m^3 increase in $PM_{2.5}$. Evaluating life expectancy in a different manner, Baccarelli et al. (2016) conducted an ecologic study to investigate whether or not there was an association between county-level $PM_{2.5}$ concentrations and the proportion of 55−64 and 70- to 74-year-olds that survived for an additional 30 years. They started with the numbers of 55−64 and 70- to 74-year-olds in 3,034 U.S. counties in 1980 and compared it with the numbers of 85−94 and 100- to 104-year-olds in 2010 in each county, using county-level $PM_{2.5}$ estimated from a hybrid of LUR and BME and averaged from 1999−2008. They observed that counties with higher estimated $PM_{2.5}$ concentrations were associated with a lower proportion of adults reaching age 85 years or more.

11.2.3 Potential Copollutant Confounding of the $PM_{2.5}$-Mortality Relationship

In the examination of potential confounding effects of copollutants on the relationship between long-term $PM_{2.5}$ exposure and mortality, it is informative to evaluate whether $PM_{2.5}$ risk estimates are changed in copollutant models. Recent studies have examined the potential for copollutant confounding by evaluating copollutant models that include O_3 (Figure 11-20), NO_2, $PM_{10-2.5}$, SO_2, and benzene (Figure 11-21). These recent studies address a previously identified data gap by informing the extent to which effects associated with exposure to $PM_{2.5}$ are independent of co-exposure to correlated copollutants in long-term analyses.

The results for associations between long-term $PM_{2.5}$ exposure and mortality in single pollutant models and copollutant models adjusted for O_3 are shown in Figure 11-20. The correlations between $PM_{2.5}$ and O_3 exposures in the studies that conducted copollutant analyses were generally positive and moderate to strong, ranging from r = 0.49 to 0.73, except for two studies which reported a weak-to-

moderate negative correlation [$r = -0.38$; (Bentayeb et al., 2015) and $r = -0.24$; (Di et al., 2017c)]. Generally, the $PM_{2.5}$ effect estimates remained relatively unchanged in copollutant models adjusted for O_3. The trend persisted for total (nonaccidental) mortality, as well as mortality due to cardiovascular or respiratory disease. There were several exceptions to the trend. The effect of long-term $PM_{2.5}$ exposure on CHD mortality among women in the AHSMOG cohort (Chen et al., 2005) increased after adjusting for O_3 in the model. Conversely, the effect of long-term $PM_{2.5}$ exposure on respiratory mortality in the ACS cohort (Jerrett et al., 2009) decreased (and changed from positive to negative) after adjusting for O_3 in the model.

The results for associations between long-term $PM_{2.5}$ exposure and mortality in single pollutant models and copollutant models adjusted for NO_2, $PM_{10-2.5}$, SO_2, or benzene are shown in Figure 11-21. The correlations between $PM_{2.5}$ and NO_2 exposures in studies that conducted copollutant analyses were positive and weak ($r = 0.25$) or moderate ($r = 0.40$; $r = 0.55$). The correlations between $PM_{2.5}$ and $PM_{10-2.5}$ were not reported in one study (Puett et al., 2009), and in another meta-analysis, the copollutant analyses were limited to cohorts that reported a correlation of $r < 0.7$. One study evaluated SO_2 (Chen et al., 2005) and another benzene (Bentayeb et al., 2015) in copollutant models, and reported correlations of $r = 0.30$ and $r = 0.66$, respectively. Generally, the $PM_{2.5}$ effect estimates remained relatively unchanged in copollutant models adjusted for NO_2, $PM_{10-2.5}$, SO_2, or benzene.

11.2.4 Evaluation of the $PM_{2.5}$-Mortality Concentration-Response Relationship

An important consideration in characterizing the association between long-term $PM_{2.5}$ exposure and mortality is whether the concentration-response relationship is linear across the full concentration range that is encountered, or if there are concentration ranges where there are departures from linearity. The 2009 PM ISA characterized the results of an analysis by Schwartz et al. (2008) that demonstrated that the shape of the concentration-response curve was generally linear.

A number of recent studies have conducted analyses to inform the shape of the concentration-response relationship for the association between long-term exposure to $PM_{2.5}$ and mortality, and are summarized in Table 11-7. Generally, the results of these analyses continue to support a linear, no-threshold relationship for total (nonaccidental) mortality, especially at lower ambient concentrations of $PM_{2.5}$ (i.e., ≤12 μg/m^3). Lepeule et al. (2012), Di et al. (2017c) and Shi et al. (2015) observed linear, no-threshold concentration-response relationships for total (nonaccidental) mortality, with confidence in the relationship down to a concentration of 8, 5, and 6 μg/m^3, respectively (Figure 11-22). Similar linear, no-threshold concentration-response curves were observed for total (nonaccidental) mortality in other studies (Chen et al., 2016; Hart et al., 2015; Thurston et al., 2015; Cesaroni et al., 2013). Pinault et al. (2016) demonstrated that though the relationship was not statistically different than linear across the range of $PM_{2.5}$ concentrations observed in the study, the slope of the line tended to be steeper at lower concentrations (Figure 11-23), and Crouse et al. (2015) reported a supralinear model was a better fit to the data than the linear model (Figure 11-23). In contrast, Villeneuve et al. (2015) observed that the best fit for the long-term $PM_{2.5}$ exposure—total (nonaccidental) mortality relationship was in a threshold model with a threshold at 11 μg/m^3 (Figure 11-23). In addition, there is emerging evidence for a nonlinear concentration-response function for some causes of death (Section 6.3.9.2).

Table 11-7 Summary of studies examining the concentration-response relationship or conduction threshold analyses for long-term exposure to $PM_{2.5}$ and total (nonaccidental) mortality.

Study Location—Cohort Table/Figure from Reference	Exposure $PM_{2.5}$ Mean; Range in $\mu g/m^3$	Statistical Analysis Summary
†Beelen et al. (2014a) Europe–ESCAPE (Table 5; Figure on appendix pg. 51)	LUR NR; (6.6−31.0)	Cut-point Analysis—include only participants with exposure estimates below prespecified thresholds (25, 20, 15, 10 $\mu g/m^3$). Studied shape of association for each cohort by inputting exposure term as natural cubic spline. HRs remained positive and statistically significant when only participants with exposure concentrations below 25 and 20 $\mu g/m^3$ were included. Below 15 $\mu g/m^3$, HRs were elevated but less precise (i.e., wider 95% confidence intervals). Results of spline model show no deviation from linear relationship.
†Cesaroni et al. (2013) Italy–RoLS (Figure 2B)	Eulerian Dispersion Model (1 × 1 km) 23.0; (7.2−32.1)	Natural splines with 2, 3, or 4 df; compared goodness of fit using BIC and likelihood ratio test No evidence of deviation from linearity. Results similar for 2, 3 or 4 degrees of freedom
†Chen et al. (2016) Canada–EFFECT (Figure 2)	Satellite-based methods (10 × 10 km) 10.7; (1.2-18.0)	Natural splines with 2, 3, or 4 df, compared goodness of fit using AIC. Comparisons made with 2.2 $\mu g/m^3$ No evidence for departure from linearity
†Crouse et al. (2012) Canada–CanCHEC (Figure 2A-D)	Fixed-site monitors in 11 cities; Satellite-based methods (10 × 10 km) 11.2; (1.9−19.2)	Natural splines with 2, 3, or 4 df, compared goodness of fit using BIC. Log function of $PM_{2.5}$ ($\ln[PM_{2.5} + 1]$) yielded lower BIC than each of the spline models No evidence for departure from linearity. Natural spline model with 4 df had best model fit based on BIC
†Crouse et al. (2015) Canada–CanCHEC (Figures S3a)	Satellite-based methods (at postal code) 8.9; (1−18)	Restricted cubic spline functions with 2 df Natural spline fit was superior to linear model. Rather than using splines to model the concentration-response relationship across a continuous range of $PM_{2.5}$ concentrations, Beelen et al. (2014a) conducted a cut-point analysis estimating the risk of long-term $PM_{2.5}$ exposure on total (nonaccidental) mortality when only participants with assigned $PM_{2.5}$ concentrations below 25, 20, 15, and 10 $\mu g/m^3$ were included in the model. The effect estimate was relatively unchanged when only participants with concentrations below 25 and 20 $\mu g/m^3$ were included in the model. Below 20 $\mu g/m^3$ the effect estimates remained positive but became less precise (i.e., wider 95% confidence intervals) as fewer observations were included in the model. The results of this cut-point analysis support the results of a spline model that evaluated the concentration-response relationship across the entire range of concentrations observed in the study area and found a generally linear association.

Overall, the majority of evidence continues to indicate a linear, no-threshold concentration-response relationship for long-term exposure to $PM_{2.5}$ and total (nonaccidental) mortality, though some recent evidence indicates the possibility of a nonlinear concentration-response function. There is less certainty in the shape of the concentration-response curve at mean annual $PM_{2.5}$ concentrations generally below 8 $\mu g/m^3$, though some studies characterize the concentration-response relationship with certainty down to 4 $\mu g/m^3$.

11.2.5 Evaluation of Factors That May Influence $PM_{2.5}$ Associations

11.2.5.1 Comparison of Exposure Assessment Techniques

Recent studies have used a variety of both fixed-site (i.e., monitors), model (e.g., CMAQ, dispersion models) and satellite-based (e.g., aerosol optical depth [AOD] observations from satellites) methods, including hybrid methods that combine two or more fixed-site, model and/or satellite-based techniques to measure, estimate or predict $PM_{2.5}$ concentrations for use in assigning long-term $PM_{2.5}$ exposure in epidemiologic studies (see Section 3.3.2.4.3).

In a systematic comparison of fixed-site and satellite-based methods, Lee et al. (2011) concluded that, though observations were generally highly correlated, fixed-site measurements of $PM_{2.5}$ were more accurate than satellite-based observations of AOD when predicting concentrations within 98 km of the monitor, but that at distances greater than 98 km, satellite-based observations of AOD were better predictors of $PM_{2.5}$ concentrations (see Section 3.3.3 for details). In order to compare the use of fixed-site measurements and satellite-based observations of AOD, Jerrett et al. (2016) applied both methods to a common data set, the ACS cohort, and calculated effect estimates for circulatory and IHD mortality associated with $PM_{2.5}$ using both methods. They observed consistently positive associations between long-term $PM_{2.5}$ exposure and circulatory and IHD mortality, regardless of the exposure assessment technique used to assign exposure. However, they did note that when exposure assessment relied on satellite-based techniques, hazard ratios tended to be lower than when fixed-site measurements were used, or when fixed-site and satellite-based techniques were combined. Additionally, Jerrett et al. (2016)

combined all of the models into an ensemble model, weighted by model fit (i.e., AIC), and observed a 7.0% increase in circulatory mortality and a 7.5% increase in IHD mortality per 5 $\mu g/m^3$ increase in $PM_{2.5}$.

Hart et al. (2015) assigned exposure from the nearest fixed-site monitor as well as from a spatio-temporal model that included monitor observations, land use regression, and point-source emission density [see Yanosky et al. (2014) for details]. Effect estimates resulting from each exposure methods were nearly identical.

Alternately, Garcia et al. (2015) compared different exposure assessment techniques that all relied on observations from fixed-site monitors. Specifically, they evaluated assigning exposure based on the $PM_{2.5}$ concentration measured at the closest monitor, using inverse distance weighting (IDW) from multiple monitors, and by using a kriging model based on fixed-site monitor measurements. Exposure was assigned to ZIP code centroids by each exposure assessment technique. The results were consistent across exposure assessment techniques, with RRs ranging from 1.07 to 1.13 for CVD mortality, 1.20 to 1.28 for IHD mortality, and 1.01 to 1.03 for total (nonaccidental) mortality when considering the entire study area. Substantially more variability was observed for rural areas when analyses were stratified by urban and rural areas, with greater, though less precise (i.e., wider 95% confidence intervals), associations generally observed in rural areas.

A single study, Hart et al. (2015), used risk set regression calibration to correct for bias due to exposure measurement error resulting from differences in ambient concentrations and personal exposures to $PM_{2.5}$ in effect estimates for total (nonaccidental) mortality (see Section 3.4.5.2 for more detail on bias correction). They assumed that the "true" exposure was equal to the 12-month moving average for personal $PM_{2.5}$ exposure, and used percent difference in HRs ([("personal"—"ambient")/"personal"] × 100) to estimate the impact of exposure measurement error. They observed moderately higher HRs after adjusting for measurement error (1.18 vs. 1.13 from spatio-temporal exposure model; 1.22 vs. 1.12 from nearest monitor exposure model).

Overall, a number of studies demonstrate that the positive associations observed between long-term $PM_{2.5}$ exposure and mortality are robust to different methods of assigning exposure. In addition, a single study provides modest evidence that failing to correct for bias due to exposure measurement error could result in attenuated risk estimates.

11.2.5.2 Comparison of Statistical Techniques

Several recent studies have evaluated and compared the results of multiple statistical models in order to examine the robustness of the long-term $PM_{2.5}$ exposure-mortality relationship and to address concerns related to the sensitivity of results to model specification. In a reanalysis of the Harvard Six Cities study, Lepeule et al. (2012) evaluated a Cox proportional hazards model and a Poisson survival

analysis. The authors observed no substantial changes in results for the Cox models compared to the results from the Poisson survival analysis. Similarly, Thurston et al. (2016) evaluated both a traditional Cox proportional hazards model and a multilevel random-effects Cox proportional hazards model in analyses of the ACS cohort. The fully adjusted models included spatial random effects as well as contextual socio-economic variables. In addition, they examined models with random effects but not contextual variables, models with contextual variables but not random effects, and fixed effect models adjusted only for individual-level variables. The association between long-term exposure to $PM_{2.5}$ mass and IHD mortality was consistent across all of the models (HR ranged from 1.02 to 1.05). Estimates based on models without random effects and/or adjustment for contextual variables had more power and tended to be more precise. Similarities were observed in a different cohort, the NIH-AARP cohort (Thurston et al., 2015). Specifically, associations were more precise when contextual variables were not included, and the inclusion of random effects terms in the time independent Cox proportional hazards model resulted in associations similar to those observed from models without random effect terms. In an analysis of CVD mortality, Dehbi et al. (2016) used competing risk hazards regression models to allow for the influence of death from causes other than CVD. In addition, they used Cox modelling to verify that the observed results were not an artefact of using competing risk hazards regression models and observed similar results. Overall, these results from well-studied, highly regarded cohorts help to reduce uncertainties that the observed associations between long-term $PM_{2.5}$ exposure and mortality could be due to the statistical techniques employed or model specification, rather than a causal relationship.

11.2.5.3 Effects of Different Long-Term Exposure Windows

The delay between changes in exposure and changes in health has important policy implications. The 2009 PM ISA concluded that there was developing coherence in the evidence base that indicated that the health benefits from reducing air pollution could be expected within a few years of intervention (U.S. EPA, 2009). Several recent studies provide additional evidence to support this conclusion. Bentayeb et al. (2015) examined long-term exposure for four different averaging times: (1) annual mean exposure at baseline, (2) annual mean exposure 1 year before death, (3) yearly mean exposure during follow-up, and (4) average cumulative exposure from baseline through death or censure. Results for long-term $PM_{2.5}$ exposure and total (nonaccidental), cardiovascular and respiratory mortality were consistent for all four exposure windows examined. Lepeule et al. (2012) evaluated two exposure periods, 1 or 5 years before death or censure, and evaluated model fit using Akaike's Information Criterion (AIC). They observed the best fit for the 5-year exposure period. In additional sensitivity analyses, they allowed the exposure window to vary from 1 to 5 years before death or censure, and observed similar effect estimates to those in the main analysis. Using a different strategy, Wong et al. (2015) stratified the follow-up period to examine deaths occurring 2−4, 5−8, or ≥9 years after the baseline date. They observed greater risks for the period closest to the baseline date, though it is unclear if this is a result of a difference in the exposure window, or if it could be due to the age of the cohort. The cohort included participants aged 65 years or

older, and there is evidence indicating that risk decreases for individuals over 70 or 75 years of age. Thus, it is unclear if the greater risk observed for the early exposure window is due to the exposure window itself, or the age of participants during that exposure window. Overall, new evidence from recent studies continues to support the previous conclusion that health benefits from reducing air pollution could be expected with a few years of intervention.

11.2.6 Associations between $PM_{2.5}$ Sources and Components and Mortality

The 2009 PM ISA (U.S. EPA, 2009) included one study that examined the association between long-term exposure to $PM_{2.5}$ components and mortality (Lipfert et al., 2006). Integrating across health endpoints, the 2009 PM ISA concluded that there is not sufficient evidence to differentiate the components or sources more closely related to health outcomes when compared with $PM_{2.5}$ mass. A number of recent studies have examined the relationship between long-term exposure to PM components and mortality. A number of these studies estimate the risk associated with individual components of $PM_{2.5}$ (Figure 11-24), while others evaluate the potential for $PM_{2.5}$ composition to explain some of the regional/geographic heterogeneity observed in the risk estimates from studies of long-term $PM_{2.5}$ exposure.

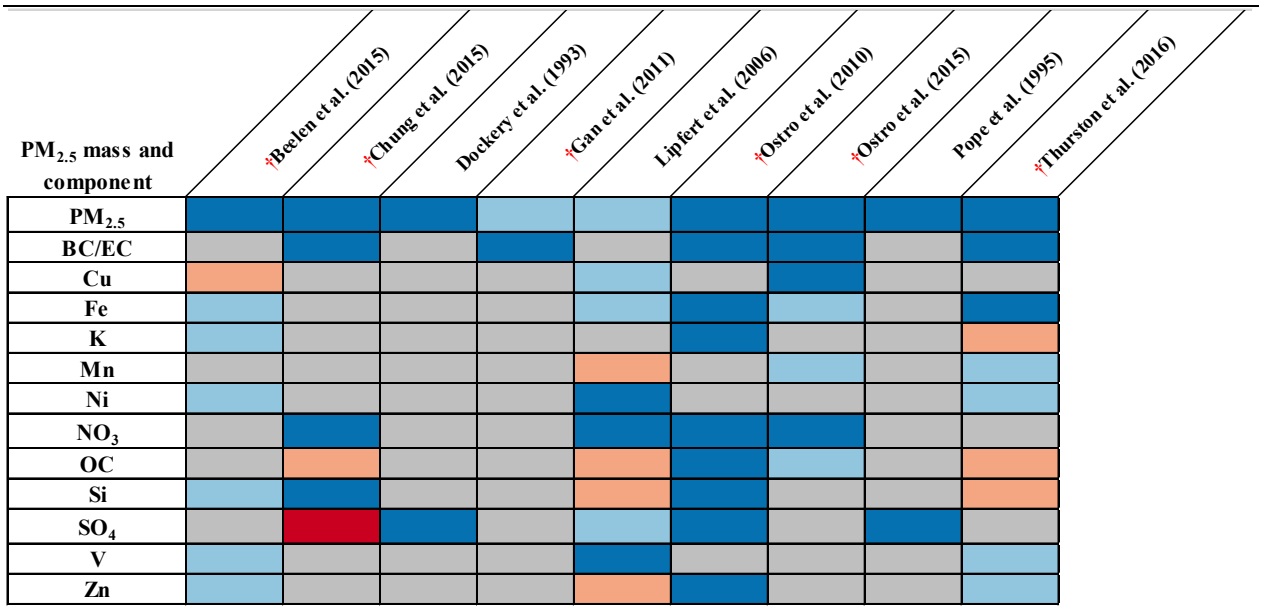
In an additional analysis of the CanCHEC cohort (described previously in Section 11.2.2.2), Crouse et al. (2016) used a novel method to calculate the risk of total (nonaccidental) and cardio-metabolic mortality associated with long-term exposure to $PM_{2.5}$ adjusted for the proportion of six individual $PM_{2.5}$ components (i.e., sulfate, nitrate, ammonium, OC, BC, dust). They observed that models of $PM_{2.5}$ mass alone were a better predictor of mortality than models of the combination of $PM_{2.5}$ mass and the proportion of any one of the six components they evaluated, but that models including the combination of $PM_{2.5}$ mass and the proportion of all six of the components were better predictors of mortality than models of $PM_{2.5}$ mass alone. In separate analyses of the CanCHEC cohort, authors collected $PM_{2.5}$ filters from 30 fixed-site monitors between 2012 and 2013 and evaluated the oxidative potential of the nonvolatile portion of $PM_{2.5}$ mass on the filter via antioxidant (glutathione and ascorbate) depletion tests (Weichenthal et al., 2016). When the $PM_{2.5}$ glutathione-related oxidative burden was estimated, the results were similar to those for $PM_{2.5}$ mass, though generally higher in magnitude. Generally null or negative hazard ratios were observed for all-cause and cause-specific mortality when $PM_{2.5}$ ascorbate-related oxidative burden was analyzed. Although not entirely consistent, these oxidative burden results may help to explain the potential for low concentrations of $PM_{2.5}$ to cause disease or to help explain geographic heterogeneity observed with $PM_{2.5}$-mortality associations.

A meta-analysis of European cohorts (i.e., the ESCAPE study, described previously in Table 11-6), evaluated mortality due to incident IHD events and eight different $PM_{2.5}$ components: S, K, Cu, Fe, Ni, V, Zn, and Si (Wolf et al., 2015). These authors used LUR to estimate $PM_{2.5}$ and component

concentrations, and cross validation of the models revealed variable performance, with some models performing poorly (i.e., $R^2 < 0.30$) and others performing moderately (i.e., $R^2 = 0.30–0.50$). The authors calculated single-component hazard ratios, as well as $PM_{2.5}$-adjusted hazard ratios, by regressing total PM on each component separately and then including the residual for each component in a model with total $PM_{2.5}$, using the estimate of the residual component to represent the independent component effect. Previous analyses of the ESCAPE cohort observed associations between long-term $PM_{2.5}$ exposure and CVD mortality. The results presented by Wolf et al. (2015) are consistent with these associations, and provide additional evidence for associations with K, Si and Fe, which could represent the resuspended road dust portion of $PM_{2.5}$. In sensitivity analyses where only cohorts for which the cross validation of the LUR model was ≥0.50, the results were relatively unchanged.

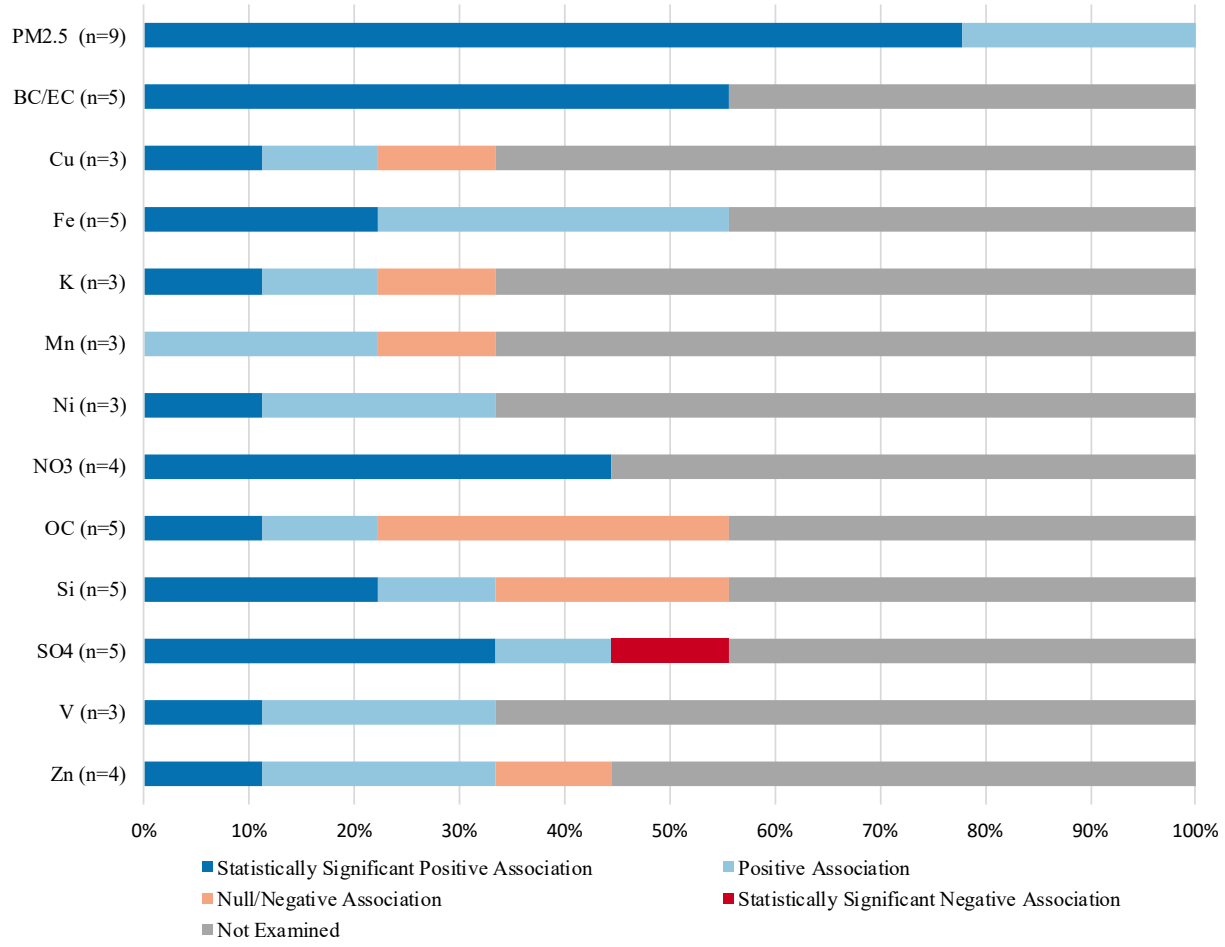
The evaluation of the association between $PM_{2.5}$ components and mortality is complicated by the different methods applied across studies. As a result, the systematic standardization of results across studies (i.e., per 5 $\mu g/m^3$ increase), as is the convention throughout this ISA, is not possible when evaluating results for $PM_{2.5}$ components. Overall, the results for individual $PM_{2.5}$ components across studies are generally more imprecise than the results for $PM_{2.5}$ (i.e., much wider confidence intervals, often including the null value), which make the individual results, as well as results across studies, more difficult to interpret. As such, for the purposes of characterizing results with respect to $PM_{2.5}$ components a different convention is employed to evaluate the pattern of associations across studies. Specifically, risk estimates from studies are classified into four categories in Figure 11-24 and Figure 11-25: (1) statistically significant positive associations; (2) positive associations, regardless of width of the confidence interval; (3) null or negative association; and (4) statistically significant negative association. Figure 11-24 and Figure 11-25 demonstrate consistent positive associations for total (nonaccidental) mortality and exposure to $PM_{2.5}$, BC/EC, Fe, Ni, NO_3^-, and V, with more studies evaluating $PM_{2.5}$, BC/EC and NO_3^-, and fewer studies examining the metals Fe, Ni, and V. Based on the pattern of results across this limited number of studies, it is difficult to disentangle the independent effect of any of these components from the effect of $PM_{2.5}$ mass.

Thurston et al. (2016) used source apportionment to evaluate the relationship between air pollution sources and IHD mortality in the ACS cohort. Sources were categorized based on source-identifier elemental tracers. They observed the strongest associations coal burning (HR: 1.05, 95% CI: 1.02, 1.08) and other combustion sources, and diesel traffic (HR: 1.03, 95% CI: 1.00, 1.06). Generally null associations were observed for other sources (i.e., wind-blown soil and biomass combustion). These results are generally consistent with previous studies of short-term exposure and mortality that have used source apportionment methods; previous studies have not considered long-term exposure and IHD mortality.



Note: †$PM_{2.5}$ component studies published since the 2009 PM ISA. Results are for total (nonaccidental) mortality except for Gan et al. (2011), who examine CVD mortality. Dark blue = study reported statistically significant positive association; Light blue = study reported a positive association regardless of width of confidence intervals; Light orange = study reported null or negative association; Red = study reported statistically significant negative association; Gray = study did not examine individual component. Only those $PM_{2.5}$ components that were examined in at least three studies are included in this figure.

Figure 11-24 Heat map of associations observed between $PM_{2.5}$ and $PM_{2.5}$ components and mortality.



n = number of studies that provided an estimate for $PM_{2.5}$ mass and individual $PM_{2.5}$ components.

Note: Bars represent the percent of associations across studies for $PM_{2.5}$ mass or $PM_{2.5}$ components detailed in Figure 11-24 that are statistically significant positive (dark blue), positive (light blue), null/negative (light orange), statistically significant negative (red), or not examined (gray).

Figure 11-25 Distribution of mortality associations for $PM_{2.5}$ and $PM_{2.5}$ components examined in studies detailed in Figure 11-24.

11.2.7 Summary and Causality Determination

Recent cohort studies evaluated since the completion of the 2009 PM ISA continue to provide consistent evidence of positive associations between long-term $PM_{2.5}$ exposures and total (nonaccidental) mortality from studies conducted mainly in North America and Europe. Many recent analyses further evaluated the association between long-term $PM_{2.5}$ exposures and the risk of mortality based on the original ACS study (Pope et al., 1995), adding new details about deaths due to cardiovascular disease (including IHD) and respiratory disease (including COPD), and extending the follow-up period of the ACS to 22 years (1982−2004). Adding to this evidence, recent U.S. and Canadian cohort studies

demonstrate consistent, positive associations between long-term $PM_{2.5}$ exposure and mortality across various spatial extents, exposure assessment metrics, and statistical techniques, and locations, where mean annual average concentrations are ≤12 μg/m^3 (Section 11.2.2.2). Additionally, the evidence from recent studies reduce uncertainties related to potential copollutant confounding (Section 11.2.3) and continues to provide strong support for a linear, no-threshold C-R relationship (Section 11.2.4). The body of evidence for total mortality is supported by generally consistent positive associations with cardiovascular and respiratory mortality. There is coherence of effects across the scientific disciplines (i.e., animal toxicological, controlled human exposure studies, and epidemiologic) and biological plausibility for $PM_{2.5}$-related cardiovascular (Chapter 6) respiratory (Chapter 5) and metabolic (Chapter 7) disease, which supports the $PM_{2.5}$-mortality relationship. This section describes the evaluation of evidence for total (nonaccidental) mortality, with respect to the causality determination for long-term exposures to $PM_{2.5}$ using the framework described in Table II of the Preamble to the ISAs (U.S. EPA, 2015b). The key evidence, as it relates to the causal framework, is summarized in Table 6-89.

The strongest evidence supporting the conclusion of a causal relationship between long-term $PM_{2.5}$ exposure and total mortality in the 2009 PM ISA was derived from analyses of the ACS and HSC cohorts. Recent extended analyses and reanalysis of these cohorts continues to support this relationship, demonstrating consistent positive associations for total (nonaccidental mortality) and across different cause-specific mortality outcomes. A recent series of analyses of the Medicare cohort of U.S. individuals provides additional support, culminating with the largest cohort study of nearly 61 million U.S. Medicare enrollees that reports positive associations with increases in $PM_{2.5}$ concentrations and stronger associations in areas where the mean annual $PM_{2.5}$ concentrations are ≤12 μg/m^3 (Di et al., 2017c). Another recent series of studies conducted in Canada provides results consistent with those of the Medicare cohort (i.e., positive associations between long-term $PM_{2.5}$ exposure and total mortality in areas where mean annual $PM_{2.5}$ concentrations are ≤12 μg/m^3. One difference between these studies is that the Canadian cohorts include all adults (aged 25+ years) and the Medicare cohort only includes adults aged 65+ years, demonstrating that these effects are not specific to one lifestage, but affect all adults. Also, an additional line of evidence is available that includes results from a number of cohorts that recruited subjects based on their place of employment, including female nurses, female teachers, male health professionals, and male truck drivers, which observe consistent, positive associations between long-term $PM_{2.5}$ exposure and total mortality.

Table 11-8 Summary of evidence for a causal relationship between long-term $PM_{2.5}$ exposure and total mortality.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Consistent epidemiologic evidence from multiple, high-quality studies at relevant $PM_{2.5}$ concentrations	Positive associations between long-term $PM_{2.5}$ exposure and mortality in the multiple analyses of the ACS and HSC cohorts, with effect estimates similar in magnitude, even after adjustment for common potential confounders.	Section 11.2.2.1	Mean concentrations across studies: 11.4−23.6 μg/m^3
	Positive associations between long-term $PM_{2.5}$ exposure and mortality in the multiple analyses of the Medicare cohort, with effect estimates similar in magnitude, even after adjustment for common potential confounders.	Section 11.2.2.2	Mean concentrations across studies: 8.12−12.0 μg/m^3
	Positive associations between long-term $PM_{2.5}$ exposure and mortality in the multiple analyses of Canadian cohorts, with effect estimates similar in magnitude, even after adjustment for common potential confounders.	Section 11.2.2.2	Mean concentrations across studies: 8.7−9.1 μg/m^3
	Positive associations between long-term $PM_{2.5}$ exposure and mortality in the multiple North American occupational cohorts, even after adjustment for common potential confounders.	Section 11.2.2.2	Mean concentrations across studies: 12.7−17.0 μg/m^3
	Positive associations with cardiovascular, respiratory, and lung cancer mortality.	Section 6.3.10.1	Mean (across studies): 4.1−17.9 μg/m^3
		Section 5.2.10	Mean (across studies): 4.1−17.9 μg/m^3
		Section 10.2.5.1	Mean (across studies): 6.1−33.7 μg/m^3

Table 11-8 (Continued): Summary of evidence indicating that a causal relationship exists between long-term $PM_{2.5}$ exposure and total mortality.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Epidemiologic evidence from copollutant models provides some support for an independent $PM_{2.5}$ association	Positive associations observed between long-term $PM_{2.5}$ exposure and total mortality remain relatively unchanged after adjustment for O_3, NO_2 and $PM_{10-2.5}$ When reported, correlations with copollutants were highly variable (low to high).	Section 1.1.1.1; Figure 11-20; Figure 11-21	
Consistent positive epidemiologic evidence for associations between $PM_{2.5}$ exposure and total mortality across exposure measurement metrics	Positive associations consistently observed across studies that used fixed-site (i.e., monitors), model (e.g., CMAQ, dispersion models) and satellite-based (e.g., AOD observations from satellites) methods, including hybrid methods that combine two or more of these methods.	Section 11.2.2.6; Jerrett et al. (2016)	
Epidemiologic evidence supports a linear, no-threshold concentration-response (C-R) relationship	No evidence for deviation from linearity in several U.S. and Canadian cohorts	Section 11.2.2.4	

Table 11-8 (Continued): Summary of evidence indicating that a causal relationship exists between long-term $PM_{2.5}$ exposure and total mortality.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Biological plausibility from studies of cardiovascular and respiratory morbidity and lung cancer incidence and mortality	Cardiovascular morbidity studies provide expanded body of evidence for associations between long-term $PM_{2.5}$ exposure and CHD, stroke and atherosclerosis, providing biological plausibility for a relationship between long-term $PM_{2.5}$ exposure and cardiovascular mortality.	Section 6.3 Miller et al. (2007) Chi et al. (2016)	Mean (across studies): 10.7−13.4 μg/m^3
	Respiratory morbidity studies provide some evidence for an association between long-term $PM_{2.5}$ exposure and development of COPD, providing limited biological plausibility for a relationship between long-term $PM_{2.5}$ exposure and respiratory mortality	Section 5.2.5	
	Consistent epidemiologic evidence for associations between $PM_{2.5}$ exposure and lung cancer incidence and mortality in cohort studies conducted in the U.S., Canada, Europe and Asia	Section 10.2.5.1 Figure 10-3	Mean (across U.S. and Canadian studies): 6.3−23.6 μg/m^3

ACS = American Cancer Society; AHSMOG = Adventist Health Study of Smog; AOD = aerosol optical depth; CO = carbon monoxide; EC = elemental carbon; HSC = Harvard Six Cities; MI = myocardial infarction; NLCS = Netherlands Cohort Study on Diet and Cancer; NO_2 = nitrogen dioxide; ppb = parts per billion; $PM_{2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 2.5 μm; PM_{10} = particulate matter with a nominal aerodynamic diameter less than or equal to 10 μm; $PM_{10-2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 10 μm and greater than a nominal diameter of 2.5 μm; SO_2 = sulfur dioxide.

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Table I and Table II of the Preamble.

[b]Describes the key evidence and references contributing most heavily to the causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where the full body of evidence is described.

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

Recent evidence helps to reduce uncertainties related to potential copollutant confounding of the relationship between long-term $PM_{2.5}$ exposure and mortality. Multiple studies evaluated ozone (Figure 11-20) and NO_2 (Figure 11-21) in copollutant models and observed similar hazard ratios for $PM_{2.5}$ regardless of whether ozone or NO_2 were included in the model. This supports an independent effect of long-term $PM_{2.5}$ exposure on mortality. Evidence for other potential copollutants (e.g., SO_2, CO) is limited.

Recent studies have used a variety of both fixed-site (i.e., monitors), model (e.g., CMAQ, dispersion models) and satellite-based [e.g., aerosol optical depth (AOD) measurements from satellites] methods, including hybrid methods that combine two or more fixed-site, model and/or satellite-based techniques to measure, estimate or predict $PM_{2.5}$ concentrations for use in assigning long-term $PM_{2.5}$ exposure in epidemiologic studies. Overall, the exposure assessment technique has had little influence on study results, with consistently positive associations of similar magnitude observed across studies using a variety of exposure assessment techniques. Notably, Jerrett et al. (2016) applied fixed-site measurements and satellite-based observations of AOD to a common data set, the ACS cohort, and calculated effect estimates for circulatory and IHD mortality associated with $PM_{2.5}$ using both methods. They observed consistently positive associations between long-term $PM_{2.5}$ exposure and mortality, regardless of the exposure assessment technique used to assign exposure. Additionally, Jerrett et al. (2016) combined multiple exposure assessment techniques into an ensemble model, weighted by model fit, and continued to observe similar positive associations with mortality. These results support an independent effect of long-term $PM_{2.5}$ exposure on mortality that is not overtly influenced by or a residual of the exposure assessment technique used in the study.

The number of studies examining the shape of the C-R function for long-term $PM_{2.5}$ exposure and mortality has substantially increased since the 2009 PM ISA. These studies used a number of different statistical techniques to evaluate the shape of the C-R function, including natural cubic splines, restricted cubic splines, penalized splines, thin-plate splines, and cut-point analyses (Table 11-7), and generally observe linear, no-threshold relationships down to 4−8 $\mu g/m^3$. Few studies have conducted extensive analyses exploring alternatives to linearity when examining the shape of the $PM_{2.5}$-mortality C-R relationship. Among these studies, there is some emerging evidence for a supra-linear C-R function, with steeper slopes observed at lower $PM_{2.5}$ concentrations. Though few, such supra-linear C-R functions are most commonly observed for cardiovascular mortality compared to total (nonaccidental) or respiratory mortality.

The 2009 PM ISA concluded that there is not sufficient evidence to differentiate the components or sources more closely related to health outcomes when compared with $PM_{2.5}$ mass, though the evidence for long-term exposure and mortality was limited. More recently, a number of studies examined the relationship between long-term exposure to PM components and mortality (Figure 11-24). Collectively, recent studies continue to demonstrate that no individual $PM_{2.5}$ component or source is a better predictor of mortality than $PM_{2.5}$ mass.

Overall, recent epidemiologic studies build upon and further reaffirm the conclusions of the 2009 PM ISA for total mortality. The evidence particularly from the assessment of $PM_{2.5}$-related cardiovascular and metabolic diseases, with more limited evidence from respiratory morbidity, provides biological plausibility for mortality due to long-term $PM_{2.5}$ exposures. In conclusion, the consistent positive associations observed across cohort studies conducted in various locations across North America are further supported by the results from copollutant analyses indicating robust associations independent of

O_3 and NO_2. **Collectively, this body of evidence is sufficient to conclude that a causal relationship exists between long-term $PM_{2.5}$ exposure and total mortality.**

11.3 Short-Term $PM_{10–2.5}$ Exposure and Total Mortality

The 2009 PM ISA concluded that the evidence is "suggestive of a causal relationship between short-term exposure to $PM_{10–2.5}$ and mortality" (U.S. EPA, 2009).[80] This evidence was based on generally consistent, positive associations across mortality outcomes from primarily single-city studies, with some additional evidence from a few multicity studies, conducted in the U.S. and Canada. However, there was uncertainty with respect to the associations observed across epidemiologic studies due to the different methods used to measure $PM_{10–2.5}$ concentrations, which included direct measurements of $PM_{10–2.5}$ using dichotomous samplers and calculating the difference between PM_{10} and $PM_{2.5}$ concentrations (e.g., at collocated monitors, taking the difference between area-wide averages of PM_{10} and $PM_{2.5}$). Compared to studies of $PM_{2.5}$, there were relatively few studies that conducted additional analyses to further examine the $PM_{10–2.5}$-mortality relationship, resulting in the inability to adequately assess potential copollutant confounding, as well as the influence of model specification, seasonal associations, and effect measure modification. Additionally, there was a lack of information on the chemical and biological components that comprise $PM_{10–2.5}$.

Since the completion of the 2009 PM ISA a number of new studies, with the majority being multicity, conducted in diverse geographic locations (e.g., U.S., Asia, and Europe) have examined the relationship between short-term $PM_{10–2.5}$ exposure and mortality. However, the relative number of studies focusing on short-term $PM_{10–2.5}$ exposure and mortality has remained small, with many of the studies still using rather crude approaches to estimating exposures to $PM_{10–2.5}$. As detailed in Section 11.2.1 on short-term $PM_{2.5}$ exposure and mortality, this section on $PM_{10–2.5}$ and mortality focuses primarily on multicity studies because they examine the association between short-term $PM_{2.5}$ exposure and a health effect over a large geographic area that consists of diverse atmospheric conditions and population demographics, using a consistent statistical methodology, which avoids the potential publication bias often associated with single-city studies (U.S. EPA, 2008). Other recent studies (i.e., single and multicity) that do not further inform uncertainties or limitations in the short-term $PM_{10–2.5}$ exposure and mortality evidence are not the focus of this section, and are available at: https://hero.epa.gov/hero/particulate-matter.

The following section provides a brief overview of the associations observed in recent studies of mortality and short-term $PM_{10–2.5}$ exposures, with the main focus on evaluating whether recent studies address the uncertainties and limitations identified in the 2009 PM ISA (U.S. EPA, 2009), specifically: copollutant confounding; model specification; effect modification (e.g., temperature, season); exposure

[80] As detailed in the Preface, risk estimates are for a 10 $\mu g/m^3$ increase in 24-hour average $PM_{10–2.5}$ concentrations, unless otherwise noted.

assessment; and the concentration-response relationship and related issues (e.g., lag structure of associations). The multicity studies discussed throughout this section, along with study-specific details, air quality characteristics, and the approach used to estimate $PM_{10-2.5}$ concentrations are highlighted in Table 11-9.

Table 11-9 Study-specific details and $PM_{10-2.5}$ concentrations from multicity studies in the 2009 PM ISA and 2004 PM air quality criteria document (AQCD), and recent multicity studies and meta-analyses.

Study	Mortality Outcome(s)	Mean Concentration µg/m^3	Upper Percentile Concentrations µg/m^3	Measurement of $PM_{10-2.5}$ Concentrations	Copollutant Examination
Klemm and Mason (2003)[a] Six U.S. cities (1979–1988)	Total	9.0[b]	75th: 15.5 Max: 30.1	$PM_{10-2.5}$ directly measured using dichotomous samplers[c]	Correlation (*r*): NA Copollutant models with: NA

[a]Multicity studies included in the 2004 PM AQCD.

[b]Median concentration.

[c]Until 1984 consisted of particles with aerodynamic diameter greater than 2.5 μm and less than 15 μm, and after first quarter 1984 upper end was less than 10 μm (Klemm et al., 2000).

[d]PM only measured in 4 of the 5 cities.

[e]Stafoggia et al. (2017) did not report quantitative estimates for cardiovascular and respiratory mortality.

†Studies published since the 2009 PM ISA.

11.3.1 Biological Plausibility for Short-Term $PM_{10-2.5}$ Exposure and Total Mortality

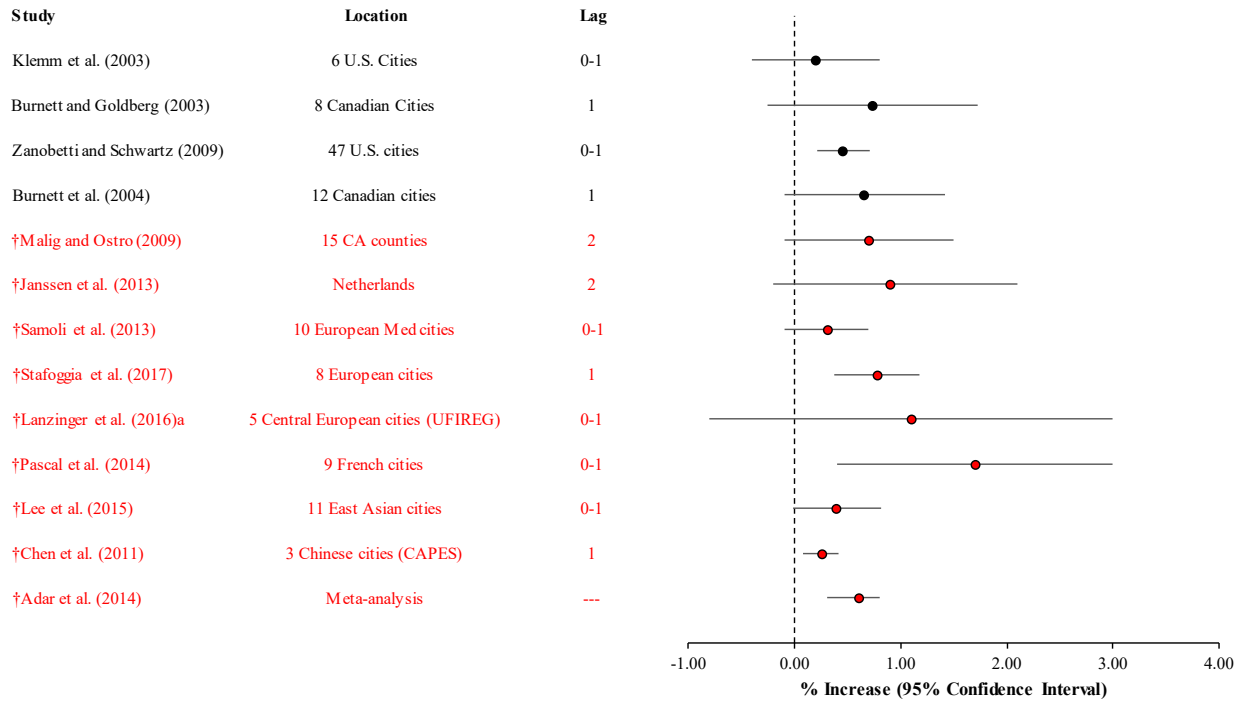
The preceding chapters characterized evidence related to evaluating the biological plausibility by which short-term $PM_{10-2.5}$ exposure may lead to the morbidity effects that are the largest contributors to total (nonaccidental) mortality, specifically cardiovascular and respiratory morbidity (Section 6.3.1 and Section 5.3.1, respectively). This evidence is derived from animal toxicological, controlled human exposure, and epidemiologic studies. Section 6.3.1 outlines the available evidence for plausible mechanisms by which inhalation exposure to $PM_{10-2.5}$ could result in initial events, such as an inflammatory response in the lungs, as well as systemic inflammation and altered hemostasis. Currently, evidence is lacking for progression to intermediate endpoints (e.g., endothelial dysfunction) and population outcomes (e.g., IHD, emergency department [ED] visits, and hospital admissions) that are observed in experimental and observational health studies. Similarly, Section 5.3.1 characterizes the available evidence by which inhalation exposure to $PM_{10-2.5}$ could progress from initial events to endpoints relevant to the respiratory system. There is some evidence for an initial event characterized by inflammatory responses that could support progression along an inflammation-mediated pathway. However, the evidence for how the initial events and subsequent endpoints could lead to increases in respiratory ED visits and hospital admissions is limited. Collectively, the progression demonstrated in the available evidence for cardiovascular and respiratory morbidity supports potential biological pathways by which short-term $PM_{10-2.5}$ exposures could result in cardiovascular and respiratory morbidity, but there is still uncertainty related to how these initial events could progress to more severe endpoints, including mortality.

11.3.2 Associations between Short-Term $PM_{10-2.5}$ Exposure and Total (Nonaccidental) Mortality in All-Year Analyses

Recent multicity studies that examined the relationship between short-term $PM_{10-2.5}$ exposure and total (nonaccidental) mortality have primarily been limited to Europe and Asia. The results from these studies, along with a meta-analysis, build on the relatively consistent, positive associations observed in multicity studies evaluated in the 2009 PM ISA and 2004 PM AQCD (Figure 11-26). It is worth noting that in the meta-analysis by Adar et al. (2014) an examination of publication bias indicated that estimates for $PM_{10-2.5}$ showed possible evidence of publication bias, which was not observed for $PM_{2.5}$ and may contribute to the small literature base for $PM_{10-2.5}$.

Consistent with the 2009 PM ISA, across studies different methods were used to measure $PM_{10-2.5}$ concentrations with most studies relying on some form of the difference method (i.e., subtracting PM_{10} concentrations from $PM_{2.5}$ concentrations) (Table 11-9). Although some studies have attempted to examine the relationship between different $PM_{10-2.5}$ monitoring methods as detailed in Section 2.4.2, these

analyses are limited to a few locations and it remains unclear how similar the absolute magnitude of $PM_{10-2.5}$ concentrations are across each method and whether the $PM_{10-2.5}$ concentrations estimated from each method are temporally correlated.



CAPES = China Air Pollution and Health Effects Study; UFIREG = Ultrafine Particles—an evidence based contribution to the development of regional and European environmental and health policy.

[a]Only four of the five cities measured $PM_{2.5}$.

Red circles = Multicity studies and meta-analyses published since the completion of the 2009 PM ISA. Corresponding quantitative results are reported in Supplemental Table S11-9 (U.S. EPA, 2018b).

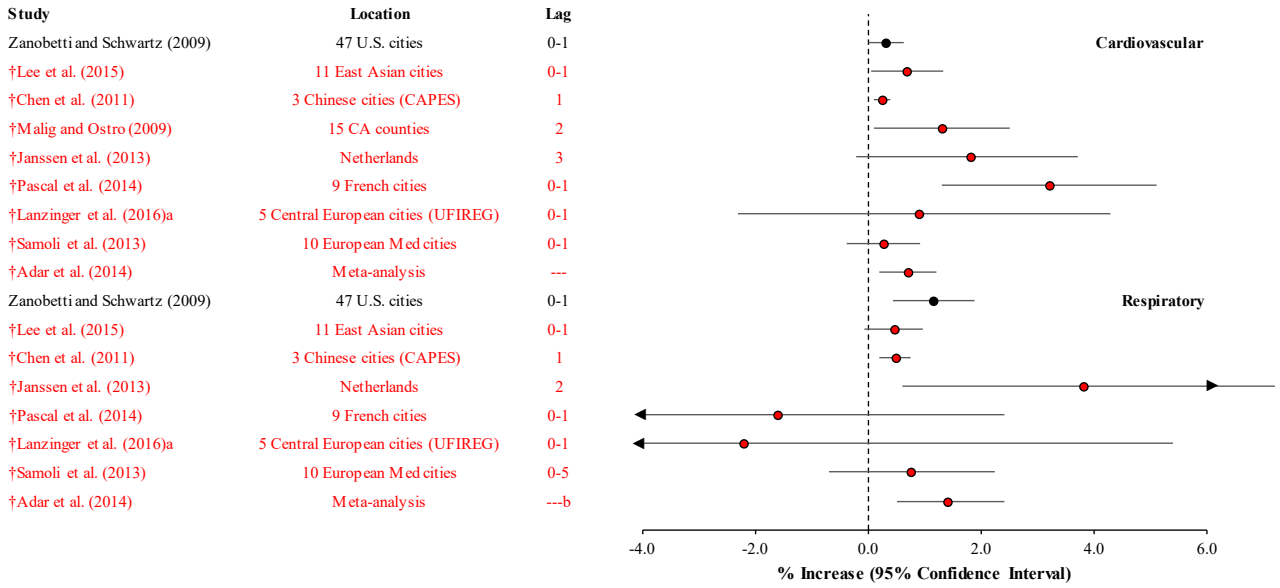
Figure 11-26 Summary of associations between short-term $PM_{10-2.5}$ exposure and total (nonaccidental) mortality in multicity studies for a 10 μg/m³ increase in 24-hour average concentrations.

11.3.3 Associations between Short-Term $PM_{10-2.5}$ Exposure and Cause-Specific Mortality in All-Year Analyses

In addition to evaluating the relationship between short-term $PM_{10-2.5}$ exposure and total (nonaccidental) mortality a number of studies also evaluated cause-specific mortality (i.e., cardiovascular and respiratory mortality) (U.S. EPA, 2009). Studies that examined cardiovascular mortality reported

evidence of consistent positive associations. Fewer studies examined the association between short-term $PM_{10–2.5}$ exposure and respiratory mortality, with most, but not all studies reporting positive associations. Across both cardiovascular and respiratory mortality studies confidence intervals were larger than those observed for total (nonaccidental) mortality, which is a reflection of a majority of studies consisting of single-city studies.

Recent multicity studies add to the body of evidence detailed in the 2009 PM ISA (Figure 11-27). An examination of cardiovascular mortality finds evidence of consistent positive associations, but both the magnitude of the association along with the width of the 95% confidence intervals vary across studies. For respiratory mortality, most, but not all studies, reported evidence of positive associations. However, similar to the examination of cardiovascular mortality and short-term $PM_{10–2.5}$ exposures, the confidence intervals were large for some studies, particularly Janssen et al. (2013) and Lanzinger et al. (2016), which could be attributed to the rather short time-series for both studies.



CAPES = China Air Pollution and Health Effects Study; UFIREG = Ultrafine Particles—an evidence based contribution to the development of regional and European environmental and health policy.

[a]Only four of the five cities measured $PM_{2.5}$, study included ages >1.

[b]Adar et al. (2014) focused on single-day lag results, specifically lag 0, 1, or 2.

11.3.4 Potential Confounding of the $PM_{10-2.5}$-Mortality Relationship

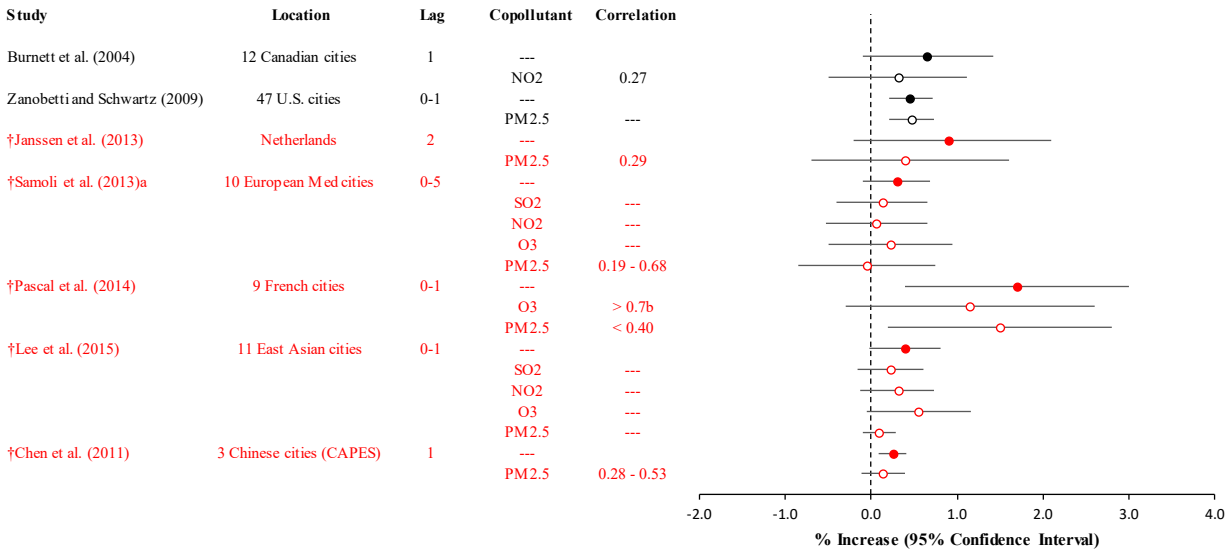
At the completion of the 2009 PM ISA, there was relatively little information on the potential confounding effects of other pollutants (i.e., both gaseous as well as $PM_{2.5}$) along with weather covariates on the $PM_{10-2.5}$-mortality relationship. As often detailed in air pollution epidemiology, a thorough evaluation of potential confounding by both copollutants and weather variables is important in understanding the relationship between an air pollutant exposure and health outcome.

11.3.4.1 Copollutants

Multicity studies that evaluated potential copollutant confounding in the 2009 PM ISA were limited to studies conducted by Zanobetti and Schwartz (2009) in 47 U.S. cities and Burnett et al. (2004)

in 12 Canadian cities, which examined copollutant models with $PM_{2.5}$ and NO_2, respectively. These studies provided initial evidence that $PM_{10–2.5}$-mortality associations remained positive in copollutant models with particles and gaseous pollutants although the $PM_{10–2.5}$ measurement methods varied between the studies (Figure 11-28). Recent multicity studies expand upon the limited number of studies evaluating the potential copollutant confounding of the $PM_{10–2.5}$-mortality relationship.

As summarized in Figure 11-28, copollutant models that included $PM_{2.5}$ resulted in $PM_{10–2.5}$-mortality associations that were often attenuated and generally remained positive in analyses conducted specifically in the U.S. and Canada, but in some cases became null (Samoli et al., 2013). This observation is supported by a study conducted in California that observed $PM_{10–2.5}$ mortality associations were similar in magnitude in copollutant models with $PM_{2.5}$ (quantitative results not presented) (Malig and BD, 2009). The indication that $PM_{10–2.5}$ results generally remain positive in copollutant models with $PM_{2.5}$, as presented in Figure 11-28, is supported by analyses that examined potential copollutant confounding in the context of a meta-analysis. When examining studies that conducted copollutant models with $PM_{2.5}$, Adar et al. (2014) observed that the $PM_{10–2.5}$-mortality association was similar in magnitude to that observed in single-pollutant models (quantitative results not provided). The results from copollutant models were further supported when stratifying $PM_{10–2.5}$-mortality estimates by the correlation with $PM_{2.5}$ (low, $r < 0.35$; medium, $r = 0.35$ to < 0.5; high, $r > 0.5$). The authors observed evidence of positive associations across each stratification, although the magnitude varied, with the association being largest in magnitude for correlations <0.35. Adar et al. (2014) further examined potential copollutant confounding by $PM_{2.5}$ through an analysis focusing on whether $PM_{10–2.5}$-mortality associations were present when the correlation between $PM_{2.5}$ and $PM_{10–2.5}$ increased and when $PM_{2.5}$ was also associated with mortality. As highlighted in Figure 11-29, there was not a consistent pattern of $PM_{10–2.5}$-mortality associations when there was also evidence of a $PM_{2.5}$-mortality association.



CAPES = China Air Pollution and Health Effects Study.

[a]Copollutant results only presented for a lag of 0−5 days.

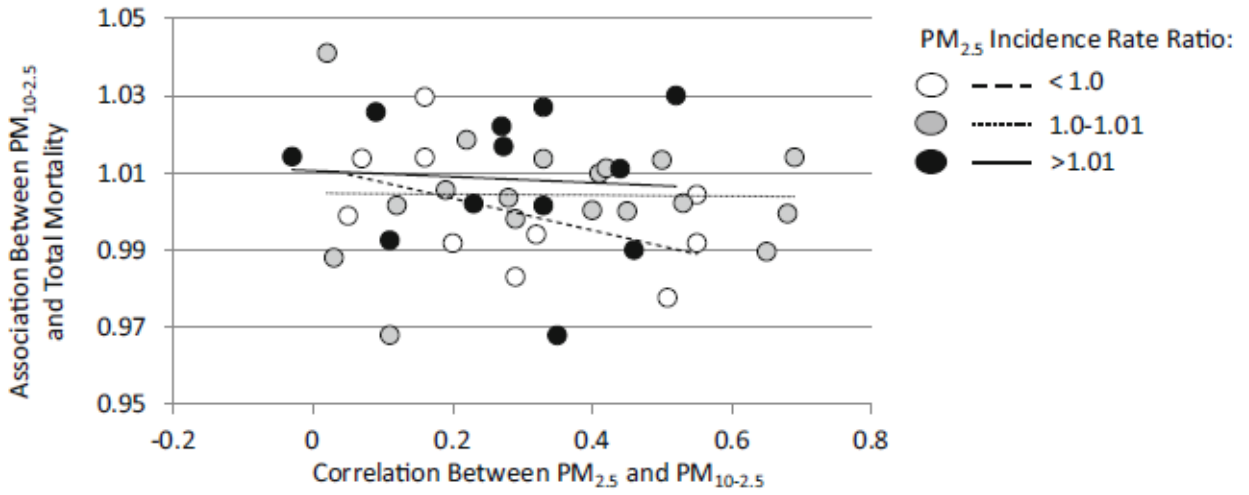
Note: †Studies published since the 2009 PM ISA. Black circles = single-pollutant model. White circles = copollutant models. Corresponding quantitative results are reported in Supplemental Table S11-11 (U.S. EPA, 2018b).

Figure 11-28 Summary of associations between short-term $PM_{10-2.5}$ exposure and total (nonaccidental) mortality for a 10 μg/m^3 increase in 24-hour average concentrations in single and copollutant models from multicity studies.



Source: Permission pending, Adar et al. (2014).

Figure 11-29 Incidence rate ratios as a function of the correlation between short-term $PM_{10-2.5}$ and $PM_{2.5}$ concentrations stratified by $PM_{2.5}$ associations.

An evaluation of copollutant models including gaseous pollutants finds that in many instances the $PM_{10-2.5}$-mortality association is robust or slightly attenuated, but remains positive across studies (Figure 11-28). However, the interpretation of results across these studies is complicated by the relative lack of information on the correlation between $PM_{10-2.5}$ and gaseous pollutants.

Collectively, recent multicity studies provide additional information on whether the $PM_{10-2.5}$-mortality association is confounded by copollutants. However, uncertainty still remains, particularly with respect to the correlation between $PM_{10-2.5}$ and gaseous pollutants, which could further inform the copollutant model results observed across studies. Overall, there is some evidence that the $PM_{10-2.5}$-mortality association remains positive in copollutant models with $PM_{2.5}$ and O_3, with a more limited number of studies examining NO_2 and SO_2.

11.3.4.2 Long-Term Temporal Trends and Weather

The studies evaluated in the 2009 PM ISA that focused on the relationship between short-term $PM_{10-2.5}$ exposure and mortality did not conduct systematic evaluations or sensitivity analyses to examine the potential influence of model specification, specifically pertaining to the control for weather and temporal trends, on the $PM_{10-2.5}$-mortality association. Although a limited evaluation of model specification for the $PM_{10-2.5}$-mortality relationship has been conducted in a few recent multicity studies, compared to $PM_{2.5}$ (see Section 11.1.5.1) the overall evaluation remains rather limited.

Of the multicity studies that examined the influence of model specification, the focus has tended to be on adequate control for temporal trends. Lee et al. (2015a) in a study consisting of 11 East Asian countries examined the influence of altering the df per year to control for temporal trends from 6 to 12. The authors observed that as the df per year increased above 8 there was evidence that the $PM_{10–2.5}$ risk estimate was attenuated, but remained positive. The results of the systematic analysis of control for temporal trends in Lee et al. (2015a) may explain those observed in Samoli et al. (2013) where risk estimates were compared across models that selected 8 df/year to control for temporal trends a priori, used the absolute sum of the residuals of the partial autocorrelation function (PACF) to control for temporal trends, or conducted a case-crossover analysis, which inherently removes the need to control for temporal trends. The authors observed that the a priori method of selecting 8 df/yr resulted in the most conservative estimate of the $PM_{10–2.5}$-mortality association, which indicates that the results of Samoli et al. (2013) are comparable to those of Lee et al. (2015a). However, without knowing the df/yr selected through the PACF method it is unclear if the results between the two studies are consistent.

Only Pascal et al. (2014) in the study of nine French cities examined the influence of alternative weather covariates on the $PM_{10–2.5}$-mortality association. The authors used two distinct approaches: (1) a traditional analysis where daily mean temperature at lag 0 and lag 1−7 days was used instead of daily maximum and minimum temperature and (2) an alternative approach using a case crossover design where referent days were matched on days with the same temperature within the same month and year as the case day. Including a covariate for mean temperature instead of daily maximum and minimum temperature resulted in a dramatic reduction in the mortality risk estimate; whereas, when controlling for temperature using the case-crossover approach, the mortality risk estimate was almost identical to that obtained using the main generalized additive Poisson model.

Collectively, the studies that examined model specification indicate some potential sensitivity in $PM_{10–2.5}$-mortality risk estimates depending the number of df/yr included to control for temporal trends and the weather covariates included in the model. To date, however, the limited number of studies that examined the influence of model specification on the $PM_{10–2.5}$-mortality relationship do not allow for a full assessment of model specification and the potential sensitivity of risk estimates.

11.3.5 Effect Modification of the $PM_{10-2.5}$-Mortality Relationship

Relatively few studies have examined effect modification of the $PM_{10–2.5}$-mortality relationship. However, consistent with studies focusing on $PM_{2.5}$ and mortality, some studies examine whether specific individual- or population-level characteristics modify the $PM_{10–2.5}$-mortality association while other studies focus more broadly on examining those factors that potentially modify that $PM_{10–2.5}$-mortality association. The evaluation of individual- or population-level characteristics that may contribute to a population being at increased risk of PM-related health effects is detailed in Chapter 12. The following

section focuses exclusively on exploring those factors that may modify and further inform the relationship between short-term $PM_{10–2.5}$ exposure and mortality.

11.3.5.1 Season and Temperature

To date, few studies have conducted seasonal analyses to examine whether there is evidence that a specific season modifies the $PM_{10–2.5}$-mortality-relationship. Lee et al. (2015a) and Samoli et al. (2013) in studies of 11 East Asian cities and 10 European Mediterranean cities, respectively, focused on warm (April−September) and cold (October−March) season analyses. In Lee et al. (2015a), the authors observed a larger association during the cold season (0.71% [95% CI: 0.17, 1.3]; lag 0−1) compared to the warm season (0.16% [95% CI: −0.32, 0.64]). These results are the opposite of those observed in Samoli et al. (2013), although confidence intervals were large, associations were larger in magnitude in the warm season over the same lag period of 0−1 days (warm: 0.57% [95% CI: −0.16, 1.3]; cold: 0.26% [95% CI: −0.43, 0.95]). Instead of dividing the year into two seasons, Pascal et al. (2014) examined associations across the four seasons and reported seasonal associations more in line with the results of Samoli et al. (2013). The authors observed positive associations in the spring, summer, and autumn, with evidence of no association in the winter, with the summer and autumn having much larger associations, 4.6% (95% CI: 2.3, 6.9) and 3.3% (95% CI: 1.3, 5.1) at lag 0−1, respectively. Although Samoli et al. (2013) and Pascal et al. (2014) reported a relatively similar pattern of seasonal $PM_{10–2.5}$-mortality associations, the results from Lee et al. (2015a) complicate the interpretation of seasonal associations across studies.

In addition to examining seasonal associations, which in some respect are a proxy for examining the influence of temperature on the relationship between $PM_{10–2.5}$ and mortality, Pascal et al. (2014) also examined through a traditional stratified analysis if the $PM_{10–2.5}$-mortality association varied between warm (i.e., defined as days above the 97.5th percentile of the temperature distribution) and nonwarm days. The authors reported some evidence of a larger association on warm days (3.9% [95% CI: −3.3, 11.7]; lag 0−1) compared to nonwarm days (1.5% [95% CI: 0.3, 2.7]). These results were further reflected when examining the interaction ratio, which portrays the extra PM effect on warm days (1.04 [95% CI: 0.98, 1.12]).

Overall there is some evidence that warmer temperatures and seasons modify the $PM_{10–2.5}$-mortality association. However, the limited number of studies that examined both the potential modifying effects of season and temperature complicate the interpretation of results across studies.

11.3.5.2 Role of Exposure Assignment and Exposure Misclassification

Compared to $PM_{2.5}$, relatively few studies have examined the role of different parameters (e.g., distance to monitor) used to assign exposures on the $PM_{10–2.5}$ mortality relationship. Although

similar approaches to assign exposure have been used across PM size fractions, it remains unclear if different parameters impact the observed association and its magnitude. Malig and BD (2009) in the case-crossover study of 15 California counties examined the influence of reducing the buffer size around monitors from 20 to 10 km on the $PM_{10-2.5}$-mortality association when assigning exposure. The authors observed the strongest association at lag 2 when using the 20-km buffers (0.7% [95% CI: −0.1, 1.5]). When restricting the analysis to 10-km buffers around monitors, which reduced the number of cases examined by 40%, the results were almost identical (quantitative results not presented).

11.3.6 $PM_{10-2.5}$-Mortality Concentration-Response (C-R) Relationship and Related Issues

11.3.6.1 Lag Structure of Associations

Studies evaluated in the 2009 PM ISA that examined the relationship between short-term $PM_{10-2.5}$ exposure and mortality often selected lags to examine a priori and did not thoroughly examine the lag structure of associations. Across these studies positive associations were often observed with mortality at lags ranging from 0 to 1 day (U.S. EPA, 2009). Recent multicity studies provide additional insight on the lag structure of associations for short-term $PM_{10-2.5}$ exposure and mortality through systematic analyses focusing on both single- and multiday lags. As detailed in Section 11.1.8.1, the focus of this section is on those studies that conducted a systematic evaluation of different lags (e.g., single-day vs. distributed or average of multiple days) and include all single days evaluated in the distributed or multiday average lags (i.e., if a study examines a distributed or multiday average lag of 0−6 days it also examines single-day lags of 0 to 6 days).

Lee et al. (2015a) in the study of 11 East Asian cities examined the lag structure of associations for short-term $PM_{10-2.5}$ exposure and mortality by focusing on same-day exposure (lag 0) and multiday lags ranging from 0−1 to 0−4 days. Across this lag structure, the authors observed the strongest association, in terms of both magnitude and precision, at lag 0−1 and an association slightly smaller in magnitude across lags ranging from 0−2 to 0−4 days (quantitative results not presented). For each of the multiday lags; however, the confidence intervals were large. The pattern of associations observed in Lee et al. (2015a) is consistent with that reported in Stafoggia et al. (2017) in a study of eight European cities that examined single-day lags ranging from 0 to 10 days. The authors observed evidence of a positive association across lags 0 to 3 days, with the strongest association at lag 1 (quantitative results not presented).

Instead of focusing on single-day lags or a series of multiday lags, Samoli et al. (2013), in a study of 10 European Mediterranean cities, took a different approach to examining the lag structure of associations by focusing on distributed lags indicative of immediate (0−1), delayed (2−5), and prolonged

effects (0−5). The authors observed the strongest association at lag 0−1 (0.30% [95%: −0.10, 0.69]), with no evidence of an association at lags 2−5 and 0−5 days.

The results from studies that examined a series of single-day lags along with studies that examined multiday lags are consistent with the collective body of evidence detailed in the 2009 PM ISA. The combination of evidence from the 2009 PM ISA along with the limited number of studies that have systematically evaluated the lag structure of associations provide initial evidence indicating that mortality effects occur at lags ranging from 0 to 1 day.

11.3.6.2 Concentration-Response Relationship and Threshold Analyses

Studies evaluated in the 2009 PM ISA did not examine the C-R relationship and whether a threshold exists between short-term $PM_{10–2.5}$ exposure and mortality. Only the recent multicity study encompassing 10 European Mediterranean cities conducted by Samoli et al. (2013) provides some insight on the $PM_{10–2.5}$-mortality C-R relationship.

Similar to the analysis for $PM_{2.5}$ detailed in Section 11.1.10, Samoli et al. (2013) conducted a threshold analysis by selecting cutpoints at 5 $\mu g/m^3$ increments along the range of $PM_{10–2.5}$ concentrations from 0−20 $\mu g/m^3$. The authors assumed there was no risk of mortality below the defined threshold value. Samoli et al. (2013) did not observe any evidence of a threshold, which was reflected in the models with the lowest deviance being those that did not assume the presence of a threshold.

In understanding the relationship between short-term $PM_{10–2.5}$ exposure and mortality it is also important to characterize the relationship along the full distribution of ambient concentrations. Studies that examine the influence of extreme events can provide insight on the $PM_{10–2.5}$-mortality relationship at the high end of the $PM_{10–2.5}$ distribution. Lee et al. (2015a) in the analysis of 11 East Asian cities examined the influence of high particle concentrations on the $PM_{10–2.5}$-mortality association through an analysis focusing on (1) the highest 0.5% $PM_{10–2.5}$ concentrations and (2) dust storms. When including the highest 0.5% $PM_{10–2.5}$ concentrations in the analysis, the authors observed an attenuation of the $PM_{10–2.5}$ mortality association at lag 0−1 from 0.35% (95% CI: −0.02, 0.81) to 0.13% (95% CI: 0.01, 0.26). The authors reported a similar observation when examining associations between dust storm (0.07% [95% CI: −0.17, 0.31]; lag 0−1) and nondust storm (0.34% [95% CI: 0.05, 0.62]) periods, which collectively indicate a potential different relationship between short-term $PM_{10–2.5}$ exposure and mortality at higher particle concentrations. The results of Lee et al. (2015a) are supported by an analysis of areas with high $PM_{10–2.5}$ concentrations in the meta-analysis by Adar et al. (2014). When stratifying results by areas with mean concentrations <10 $\mu g/m^3$, 10 to <15 $\mu g/m^3$, and >15 $\mu g/m^3$, the authors observed the smallest associations for study areas with the highest mean $PM_{10–2.5}$ concentrations.

Summary

Although studies have not focused specifically on the shape of the $PM_{10–2.5}$-mortality C-R relationship, recent studies do not provide evidence of a threshold. Additionally, studies focusing on high concentrations provide initial evidence indicating that the shape of the C-R may plateau at higher concentrations; however, there are no statistically based analyses currently available that examine the shape of the C-R relationship to support the observations from these high concentration analyses.

11.3.7 Summary and Causality Determination

Since the completion of the 2009 PM ISA a number of multicity studies conducted primarily in Europe and Asia continue to provide evidence of consistent positive associations between short-term $PM_{10–2.5}$ exposure and total (nonaccidental) mortality. Although these studies contribute to increasing the confidence in the $PM_{10–2.5}$-mortality relationship, different methods are employed across studies in the measurement of $PM_{10–2.5}$ concentrations, which continues to form the main uncertainty in the associations observed and further support that the evidence is suggestive, but not sufficient to infer, a causal relationship. While uncertainty in the measurement of $PM_{10–2.5}$ remains, recent studies provide initial evidence that informs additional uncertainties and limitations identified in the studies evaluated in the 2009 PM ISA, specifically potential copollutant confounding; effect modification (e.g., temperature, season); and the shape of the C-R relationship and whether a threshold exists. The evidence for total mortality is supported by consistent positive associations with cardiovascular mortality with less consistent evidence for respiratory mortality; however, there is limited coherence and biological plausibility for cause-specific mortality when evaluating different health endpoints across the scientific disciplines (i.e., animal toxicological, controlled human exposure studies, and epidemiologic) for both cardiovascular (Chapter 6) and respiratory (Chapter 5) morbidity. This section describes the evaluation of evidence for total (nonaccidental) mortality, with respect to the causality determination for short-term exposures to $PM_{10–2.5}$ using the framework described in Table II of the Preamble to the ISAs (U.S. EPA, 2015b). The key evidence, as it relates to the causal framework, is summarized in Table 11-10.

Table 11-10 Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between short-term $PM_{10-2.5}$ exposure and total mortality.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{10-2.5}$ Concentrations Associated with Effects[c]
Consistent epidemiologic evidence from multiple, high quality studies at relevant $PM_{10-2.5}$ concentrations.	Increases in mortality in multicity studies conducted in the U.S., Europe, and Asia Total mortality associations, supported by consistent increases in cardiovascular mortality with less consistent evidence for respiratory mortality in multicity studies conducted in the U.S., Europe, and Asia.	Section 11.3.2 Figure 11-26 Figure 11-27 Section 5.3.7 Section 6.3.8	Mean 24-h avg: U.S.: 12.3 Europe: 7–16 Asia: 10.7[d]–101 Table 11-1
Epidemiologic evidence from copollutant models provides some support for an independent $PM_{10-2.5}$ association.	$PM_{10-2.5}$ associations are generally robust, but there are some instances of attenuation in copollutant models with gaseous pollutants and $PM_{2.5}$. However, there is limited information on the correlation between $PM_{10-2.5}$ and gaseous pollutants complicating the interpretation of results. Copollutant analyses with cardiovascular and respiratory mortality are limited to studies conducted in Europe and Asia and indicate that $PM_{10-2.5}$ associations generally remain positive, although attenuated in some instances. When reported, correlations with gaseous copollutants were primarily in the low ($r < 0.4$) to moderate ($r \geq 0.4$ or <0.7) range.	Section 11.3.4.1 Figure 11-28 Section 5.3.7.1.1 Figure 5-46 Section 6.3.8 Figure 6-32	
Uncertainty regarding exposure measurement error	Across studies $PM_{10-2.5}$ concentrations are measured using a number of approaches (i.e., directly measured from dichotomous sampler, different between PM_{10} and $PM_{2.5}$ at collocated monitors, and difference of area-wide concentrations of PM_{10} and $PM_{2.5}$), which have not been compared in terms of whether they have similar spatial and temporal correlations.	Table 11-9 Section 3.3.1.1	
Epidemiologic evidence provides some support for a no-threshold concentration-response (C-R) relationship.	Initial evidence from a study conducted in Europe for a no-threshold relationship, while a study conducted in Asia along with a meta-analysis indicating that the shape of the C-R curve may be different at higher concentrations.	Section 11.3.6.2	

Table 11-10 (Continued): Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between short-term $PM_{10-2.5}$ exposure and total mortality.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{10-2.5}$ Concentrations Associated with Effects[c]
Limited biological plausibility from cardiovascular and respiratory morbidity evidence.	Cardiovascular morbidity studies provide some evidence for ischemic events from epidemiologic studies, but limited experimental evidence resulting in limited coherence and biological plausibility for $PM_{10-2.5}$-related cardiovascular effects. Collectively, there is limited biological plausibility to support a relationship between short-term $PM_{10-2.5}$ exposure and cardiovascular mortality, which comprises ~33% of total mortality.[e] Respiratory morbidity studies provide some evidence for effects on pulmonary inflammation and function, which is supported by asthma-related hospital admissions and ED visits, but overall there is limited coherence and biological plausibility for $PM_{10-2.5}$-related respiratory effects. Collectively, there is limited biological plausibility to support a relationship between short-term $PM_{2.5}$ exposure and respiratory mortality, which comprises ~9% of total mortality.[e]	Section 6.3.13 Table 6-58 Section 5.3.8 Table 5-37

[b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to the causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

[c]Describes the $PM_{2.5}$ concentrations with which the evidence is substantiated.

[d]Median concentration from Lee et al. (2015a).

[e]Statistics taken from NHLBI (2017).

The evidence from recent multicity studies of short-term $PM_{2.5}$ exposures and mortality demonstrates consistent positive associations with total (nonaccidental) mortality, with increases ranging from 0.25% (Chen et al., 2011) to 1.70% (Pascal et al., 2014) at lags of 0 to 2 day in single-pollutant models. However, across studies different approaches have been employed to measure $PM_{10-2.5}$ concentrations (i.e., directly measured from a dichotomous sampler, difference between PM_{10} and $PM_{2.5}$ at collocated monitors, and difference of area-wide concentrations of PM_{10} and $PM_{2.5}$), which have not been compared to determine if their spatial and temporal correlation are similar, contributing uncertainty to the comparison of results across studies (Section 2.4, Section 3.3.1). Recent studies expand the assessment of potential copollutant confounding of the $PM_{10-2.5}$-mortality relationship, and provide some evidence that $PM_{10-2.5}$ associations remain positive in copollutant models, but there is some evidence that associations are attenuated (Section 11.3.4.1). Overall, the assessment of potential copollutant confounding is limited due to the lack of information on the correlation between $PM_{10-2.5}$ and gaseous

pollutants and the small number of locations in which copollutant analyses have been conducted. Analyses of cause-specific mortality provide some supporting evidence for total (nonaccidental) mortality associations, but overall estimates are more uncertain (i.e., wider confidence intervals) and less consistent, specifically for respiratory mortality (Figure 11-27). For both cardiovascular and respiratory mortality there was a limited assessment of potential copollutant confounding, with the pattern of associations and uncertainties similar to those observed for total (nonaccidental) mortality. The assessment of cardiovascular (Chapter 6) and respiratory morbidity (Chapter 5) provides limited biological plausibility for $PM_{10–2.5}$-related cardiovascular and respiratory mortality.

In addition to examining potential copollutant confounding, a few studies also assessed whether statistical models adequately account for temporal trends and weather covariates. To date, this assessment remains limited, but initial evidence indicates that $PM_{10–2.5}$ associations may be sensitive to model specification. An examination of whether associations vary by season and temperature provide some evidence that $PM_{10–2.5}$-mortality associations are larger in magnitude during warmer temperatures and seasons, but this pattern was not evident across all studies (Section 11.3.5.1). Across the studies evaluated, a few conducted systematic evaluations of the lag structure of associations. These studies examined either a series of single-day lags or whether there was evidence of an immediate (lag 0−1), delayed (lag 2−5), or prolonged effect (lag 0−5), and provided initial evidence that the $PM_{10–2.5}$ is immediate (i.e., lags 0 to 1 day) (Section 11.3.6.1). At the completion of the 2009 PM ISA no studies had assessed the $PM_{10–2.5}$-mortality C-R relationship, and recent studies have only conducted cursory analyses that do not thoroughly inform the shape of the C-R curve or whether a threshold exists.

Overall, recent epidemiologic studies provide additional support of consistent positive associations between short-term $PM_{10–2.5}$ exposure and total (nonaccidental) mortality, but there remains a large degree of uncertainty due to the various approaches used to measure $PM_{10–2.5}$ concentrations. The lack of information on the spatial and temporal correlation between the various measurement approaches reduces the confidence in the associations observed across studies. Additionally, the evidence from the assessment of short-term $PM_{10–2.5}$ exposures and cardiovascular and respiratory morbidity provide limited biological plausibility for $PM_{10–2.5}$-related mortality. Although recent studies attempt to address previously identified uncertainties and limitations in the $PM_{10–2.5}$-mortality relationship, the overall assessment of potential copollutant confounding, model specification, the lag structure of associations, and the C-R relationship remains limited. **Collectively, this body of evidence is suggestive, but not sufficient to infer, that a causal relationship exists between short-term $PM_{10–2.5}$ exposure and total mortality.**

11.4 Long-Term $PM_{10–2.5}$ Exposure and Total Mortality

The 2009 PM ISA reported that the evidence was "limited to adequately characterize the association" between long-term $PM_{10–2.5}$ exposure and mortality (U.S. EPA, 2009), noting that findings

from the AHSMOG (Chen et al., 2005; McDonnell et al., 2000) and Veterans (Lipfert et al., 2006) cohorts provided limited evidence for an association, especially after adjustment for $PM_{2.5}$ in the models. Each of these studies subtracted $PM_{2.5}$ concentrations from PM_{10} concentrations to calculate a concentration for $PM_{10–2.5}$, contributing to uncertainty in their interpretation. Due to the dearth of studies examining the association between long-term $PM_{10–2.5}$ exposure and mortality, the 2009 PM ISA concluded that the evidence was "inadequate to determine if a causal relationship exists" (U.S. EPA, 2009).[81] Recent studies provide some additional evidence to inform the relationship between long-term $PM_{10–2.5}$ exposure and mortality, though they often have similar limitations to those noted for studies included in the 2009 PM ISA.

11.4.1 Biological Plausibility for Long-Term $PM_{10–2.5}$ Exposure and Total Mortality

The preceding chapters characterized evidence related to evaluating the biological plausibility by which long-term $PM_{10–2.5}$ exposure may lead to the morbidity effects that are the largest contributors to total (nonaccidental) mortality, specifically cardiovascular and respiratory morbidity and metabolic disease (Section 6.4.1, Section 5.4.1, and Section 7.4.1, respectively). This evidence is derived from animal toxicological, controlled human exposure, and epidemiologic studies. Section 6.4.1 outlines the available evidence for plausible mechanisms by which inhalation exposure to $PM_{10–2.5}$ could result in initial events, such as an inflammatory response in the lungs, and limited evidence for altered hemostasis and arterial thrombosis. Arterial thrombosis can progress to IHD and thus provides a plausible mechanism by which ED visits and hospital admissions related to IHD can occur. Similarly, Section 5.4.1 characterizes the available evidence by which inhalation exposure to $PM_{10–2.5}$ could progress from initial events to endpoints relevant to the respiratory system. This includes evidence for markers of oxidative stress and inflammation and enhanced allergen-induced responses and airway changes that could play a role in asthma development and/or exacerbation. However, the evidence for how the initial events and subsequent endpoints could lead to the observed increases in respiratory ED visits and hospital admissions is limited. Section 7.4.1 outlines the limited evidence for an initial event (i.e., pulmonary inflammation) that could initiate mechanisms by which inhalation exposure to $PM_{10–2.5}$ could progress to intermediate endpoints and eventually result in population outcomes such as metabolic disease. However, the evidence for how pulmonary inflammation could lead to metabolic disease is limited. Collectively, the progression demonstrated in the available evidence for cardiovascular and respiratory morbidity and metabolic disease provides limited support for potential biological pathways by which long-term $PM_{10–2.5}$ exposures could result in mortality.

[81] As detailed in the Preface, risk estimates are for a 5 $\mu g/m^3$ increase in annual $PM_{10–2.5}$ concentrations, unless otherwise noted.

11.4.2 Associations between Long-Term $PM_{10-2.5}$ Exposure and Mortality

Several recent U.S. cohort studies examined the association between long-term $PM_{10-2.5}$ exposure and mortality in cohorts for which subjects were recruited based on their place of employment. Puett et al. (2009) examined the association between long-term $PM_{10-2.5}$ exposure and total (nonaccidental) mortality among a cohort of female nurses in the Nurses' Health Study from 13 states in the Northeast and Midwest from 1992 through 2002. Spatio-temporal models were used to assign exposure to $PM_{2.5}$ and PM_{10}, and the $PM_{10-2.5}$ concentrations were derived via subtraction. The authors observed positive associations with total (nonaccidental) and CHD mortality, with the strongest association observed for fatal CHD events. These associations were attenuated to below the null value in copollutant models that include $PM_{2.5}$. Using a design similar to that of the Nurses' Health Study, Puett et al. (2011) investigated the effect of long-term $PM_{10-2.5}$ (derived by subtraction of $PM_{2.5}$ from PM_{10}) exposure and mortality among men enrolled in the Health Professionals cohort. Near null associations were observed for both total (nonaccidental) and CHD mortality in this cohort.

A European pooled-analysis combined data from 22 existing cohort studies and evaluated the association between long-term $PM_{10-2.5}$ exposure and total (nonaccidental) (Beelen et al., 2014a), cardiovascular (Beelen et al., 2014b), and respiratory (Dimakopoulou et al., 2014) mortality. LUR models were used to assign exposure to $PM_{2.5}$ and PM_{10}, and the $PM_{10-2.5}$ concentrations were derived via subtraction. The authors applied a common statistical protocol to data from each of the 22 cohorts, from 13 different European countries, in the first stage of the analysis and combined the cohort-specific effects in a second stage. The authors observed a near-null association between long-term $PM_{10-2.5}$ exposure and total (nonaccidental) (Beelen et al., 2014a), cardiovascular (Beelen et al., 2014b), and respiratory (Dimakopoulou et al., 2014) mortality. The strongest association was observed for the subset of cardiovascular deaths attributable to cerebrovascular disease (HR: 1.17, 95% CI: 0.9, 1.52) (Beelen et al., 2014b), though copollutant models with $PM_{2.5}$ were not reported for this comparison. Using the same exposure models used for the pooled cohort study, Dehbi et al. (2016) assigned $PM_{10-2.5}$ exposure to two British cohort studies that were pooled together to examine CVD mortality. The British cohorts included follow-up between 1989 and 2015, though $PM_{10-2.5}$ exposure estimates were available for 2010−2011. The authors observed a negative association when exposure was considered on the continuous scale, but positive associations for each quartile when exposure was categorized. However, the confidence intervals were wide and overlapping for all of the results, and the inconsistency may indicate generally null results, but instability in the model. In a separate European cohort, Bentayeb et al. (2015) used the CHIMERE chemical transport model to estimate PM_{10} and $PM_{2.5}$, and then subtracted to estimate long-term $PM_{10-2.5}$ exposure. The authors observed positive association with total (nonaccidental), cardiovascular, and respiratory mortality, though the association with total (nonaccidental) mortality was attenuated in copollutant models with $PM_{2.5}$. The associations with cardiovascular and respiratory mortality were not evaluated in copollutant models.

Recent studies are characterized in Table 11-11. While there are more studies available in this review that examine the association between long-term $PM_{10-2.5}$ exposure and mortality, the body of evidence remains limited. In addition, to date all of the studies that have examined the relationship between long-term $PM_{10-2.5}$ exposure and mortality have used the difference method to derive concentrations for $PM_{10-2.5}$, contributing to the uncertainty associated with these effect estimates. Overall, there is no consistent pattern of associations for total, cardiovascular, or respiratory mortality. In the instances where positive associations were observed for long-term $PM_{10-2.5}$ exposure and mortality, and $PM_{2.5}$ copollutant model results were reported, the $PM_{10-2.5}$ effect estimates were often attenuated but still positive after adjusting for $PM_{2.5}$.

11.4.3 Summary and Causality Determination

Since the completion of the 2009 PM ISA a number of recent cohort studies conducted primarily in the U.S. and Europe provide no consistent evidence for positive associations between long-term $PM_{10-2.5}$ exposure and total (nonaccidental) mortality. In addition to the inconsistent results, all of the studies use the difference of PM_{10} and $PM_{2.5}$ (measured at monitors or estimated from models) to estimate $PM_{10-2.5}$, which continues to be a main uncertainty in the positive associations that are observed in some cohorts and further support that the evidence is suggestive of, but not sufficient to infer, a causal relationship. An additional uncertainty is related to potential copollutant confounding; positive associations observed in the Nurses' Health Study (Puett et al., 2009), AHSMOG (McDonnell et al., 2000) and ESCAPE (Beelen et al., 2014a) cohorts were attenuated to the null when $PM_{2.5}$ was included in the model. The strongest evidence for total mortality comes from the GAZEL cohort (Bentayeb et al., 2015) in France; the authors observed a 22% increase in total mortality associated with increases in $PM_{10-2.5}$. This association remained positive in copollutant models with $PM_{2.5}$, but was attenuated and less precise. There is limited information on biological plausibility and limited coherence across scientific disciplines (i.e., animal toxicological, controlled human exposure studies, and epidemiologic) for cardiovascular (Chapter 6) and respiratory (Chapter 5) morbidity and metabolic disease (Chapter 7). This section describes the evaluation of evidence for total (nonaccidental) mortality, with respect to the causality determination for long-term exposures to $PM_{10-2.5}$ using the framework described in Table II of the Preamble to the ISAs (U.S. EPA, 2015b). The key evidence, as it relates to the causal framework, is summarized in Table 11-12.

Overall, recent epidemiologic studies provide inconsistent evidence for positive associations between long-term $PM_{10-2.5}$ exposure and total (nonaccidental) mortality. A positive association between long-term $PM_{10-2.5}$ exposure and total mortality, which remained positive in copollutant models with $PM_{2.5}$ (Bentayeb et al., 2015), provides the strongest evidence for this relationship. However, there remains a large degree of uncertainty due to the various approaches used to measure $PM_{10-2.5}$ concentrations (see Chapter 3). The lack of information on the spatial and temporal correlation between the various measurement approaches reduces the confidence in the associations observed across studies. Additionally, the evidence from the assessment of long-term $PM_{10-2.5}$ exposures and cardiovascular and respiratory morbidity and metabolic disease provide limited biological plausibility for $PM_{10-2.5}$-related mortality. Although recent studies attempt to address previously identified uncertainties and limitations in the $PM_{10-2.5}$-mortality relationship, the overall assessment of potential copollutant confounding remains limited. **Collectively, this body of evidence is suggestive of, but not sufficient to infer, a causal relationship between long-term $PM_{10-2.5}$ exposure and total mortality.**

Table 11-12 Summary of evidence that is suggestive of, but not sufficient to infer, a causal relationship between long-term $PM_{10-2.5}$ exposure and total mortality.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Evidence from multiple epidemiologic studies is generally supportive but not entirely consistent	Positive associations from several cohort studies, but not a consistent pattern of associations for total mortality	Table 11-11	Mean concentrations across cities: 4.0−27.3 μg/m^3
Uncertainty regarding epidemiologic evidence from copollutant models to support and independent $PM_{10-2.5}$ association	$PM_{10-2.5}$ effect estimates often attenuated after adjustment for $PM_{2.5}$	Section 11.3.2	
Uncertainty regarding exposure measurement error	Across studies, $PM_{10-2.5}$ concentrations are measured using a number of approaches (i.e., directly measured from dichotomous sampler, difference between PM_{10} and $PM_{2.5}$ concentrations measured at collocated monitors, and difference of area-wide concentrations of PM_{10} and $PM_{2.5}$), which have not been compared in terms of whether they have similar spatial and temporal correlations	Table 11-11 Section 3.3.1.1	
Biological plausibility from studies of cardiovascular morbidity	Expanded body of evidence provides some evidence for associations between long-term $PM_{10-2.5}$ exposure and IHD and stroke	Section 6.5.2 and Section 6.5.5	Mean (across studies): 7.3−31.0 μg/m^3

$PM_{2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 2.5 μm; $PM_{10-2.5}$ = particulate matter with a nominal aerodynamic diameter less than or equal to 10 μm and greater than a nominal diameter of 2.5 μm.

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Table I and Table II of the Preamble.

[b]Describes the key evidence and references contributing most heavily to the causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where the full body of evidence is described.

[c]Describes the $PM_{10-2.5}$ concentrations with which the evidence is substantiated.

11.5 Short-Term UFP Exposure and Total Mortality

The 2009 PM ISA concluded that the "epidemiologic evidence is inadequate to infer a causal relationship between short-term UFP exposure and mortality" (U.S. EPA, 2009). In both the 2004 PM

AQCD and the 2009 PM ISA a few studies examined the association between short-term UFP exposure and mortality with all of the studies being conducted in Europe. Across studies there was inconsistency in the lag structure of associations, which was not consistent with the lag structure observed for other PM size fractions, and the interpretation of the evidence was further complicated by the correlation between UFPs and gaseous copollutants, specifically from combustion sources. Additionally, at the completion of the 2009 PM ISA inherent limitations across all UFP epidemiologic studies was evident and also applicable to the mortality studies. Specifically, it was noted that there is a relatively limited amount of monitoring data within the U.S. that is reflected by no U.S. based studies focusing on short-term UFP exposure and mortality; limited information on the spatial and temporal variability in UFP concentrations; and limited data on the spatial and temporal evolution of UFP size distributions along with data on the composition of UFPs (U.S. EPA, 2009).

Within this ISA, the evaluation of the relationship between short-term exposure to $PM_{2.5}$ and $PM_{10–2.5}$ and mortality focuses on studies that further characterize the relationship, or addresses uncertainties and limitations in the evidence, respectively (Section 11.2.1 and Section 11.3.1). For UFPs, the literature base for all health effects, not just mortality, is much smaller than that for the other PM size fractions. An overall limitation in the health evidence that has complicated the interpretation of results across studies, both those evaluated in the 2009 PM ISA and recent studies that specifically examined associations between short-term UFP exposure and mortality, is the different exposure metrics used (i.e., number concentration [NC], mass concentration [MC], surface area concentration [SC]). As detailed in the Preface, the evaluation of the evidence for UFPs relies on studies that examine MC and SC for particles < 0.3 μm and NC any size range that includes particles <0.1 μm (see Preface).

As detailed in Section 11.1.2, within this section the discussion will focus on the evaluation of multicity studies, but a stronger reliance on large single-city studies due to most UFP and mortality studies to date occurring in individual cities. Additionally, compared to studies that examined short-term exposure to $PM_{2.5}$ and $PM_{10–2.5}$ and mortality, most recent studies of UFPs have not focused on total (nonaccidental) mortality, but instead on cause-specific mortality. As such, cause-specific mortality studies will be discussed in more detail within this section compared to the sections on $PM_{2.5}$ and $PM_{10–2.5}$. The multicity and single-city studies discussed throughout this section, along with study-specific details, air quality characteristics, including size fraction and exposure metric, and the location of UFP monitor(s) is detailed in Table 11-13.

Table 11-13 Study-specific details and UFP concentrations from studies in the 2009 PM ISA and recent studies.

[c]Particle size distribution measured winter 1991-1992 and 1995 onward, UFP measurements imputed for missing time periods.

[d]Missing data imputed.

[e]Correlations reported only for other NAAQS pollutants.

[f]Median concentration.

[g]PM only measured in four of the five cities.

[h]For one city the range was 0.02–0.5 µm.

[i]Only three cities explicitly measured particles in the ultrafine range (i.e., <100 nm), and each city had to have at least 3 years of continuous data.

[j]NC used as a proxy for UFPs because only three cities explicitly measured UFPs.

[k]Monitor used for total NC had upper size limit of 3 µm while the monitor used for the source apportionment NC collection had an upper size limit of 0.6 µm.

†Studies published since the 2009 PM ISA.

11.5.1 Biological Plausibility for Short-Term UFP Exposure and Total Mortality

The preceding chapters characterized evidence related to evaluating (to the extent possible) the biological plausibility by which short-term UFP exposure may lead to the morbidity effects that are the largest contributors to total (nonaccidental) mortality, specifically cardiovascular and respiratory morbidity (Section 6.5.1 and Section 5.5.1, respectively). This evidence is derived from animal toxicological, controlled human exposure, and epidemiologic studies. Section 6.5.1 outlines the available evidence for plausible mechanisms by which inhalation exposure to UFP could result in cardiovascular effects. Similarly, Section 5.5.1 characterizes the available evidence by which inhalation exposure to UFP could progress from initial events to endpoints relevant to the respiratory system. While there is some evidence for initial events, including injury, inflammation and oxidative stress, the evidence for how these initial events could lead to the subsequent endpoints, and eventually increases in respiratory emergency department (ED) visits and hospital admissions is limited. Collectively, there is limited available evidence for cardiovascular and respiratory morbidity supporting potential biological pathways by which short-term UFP exposures could result in mortality.

11.5.2 Associations Between Short-Term UFP Exposure and Total Mortality in Multicity Studies

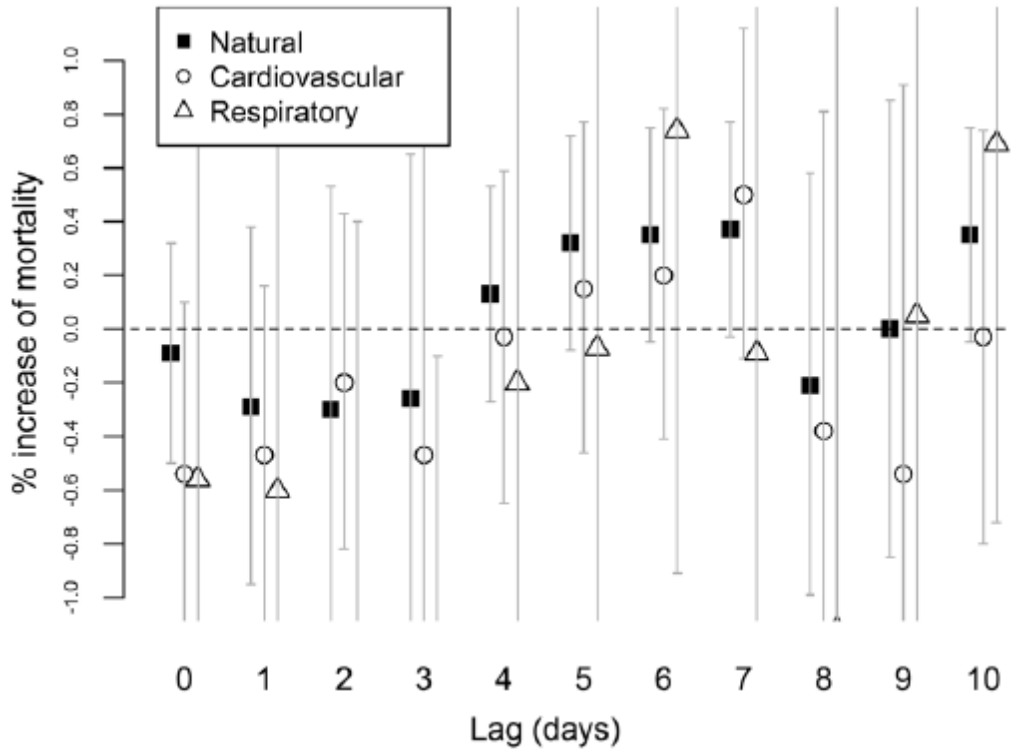
The majority of recent studies examining the association between short-term UFP exposure and mortality have primarily been conducted in individual cities. Lanzinger et al. (2016) and Stafoggia et al. (2017) represent the initial multicity studies that examine the relationship between short-term UFP exposure and mortality. Lanzinger et al. (2016) in the UFIREG project (Ultrafine particles—an evidence based contribution to the development of regional and European environmental and health policy) focused on examining short-term UFP exposure and mortality in five cities in Central and Eastern Europe, but was limited to approximately 2 years of data in each city. Stafoggia et al. (2017) examined short-term UFP exposure and mortality in a study that consisted of eight European cities mostly in Western Europe with at least 3 years of data in each city. Within Lanzinger et al. (2016) the UFP fraction was divided into two distinct metrics, and referred to as UFPs where NC was estimated for sizes ranging from 20 to 100 nm and a NC specific metric that included sizes ranging from 20 to 800 nm with one city having a smaller range of 20 to 500 nm. This approach differed from Stafoggia et al. (2017) where across cities only three explicitly measured particles within the traditional ultrafine range of <100 nm; as a result, NC was used as a proxy for UFPs in each city.

In a time-stratified case-crossover analysis, Lanzinger et al. (2016) examined immediate (lag 0−1), delayed (lag 2−5), and prolonged (lag 0−5) effects of UFP and NC exposure on mortality. Across all of the lags examined for UFP and NC, the authors observed no evidence of an association for total

(nonaccidental) or cardiovascular mortality. Lanzinger et al. (2016) reported a positive, but imprecise, association with respiratory mortality for UFP and NC across all lags with the association largest in magnitude for UFP at lag 0−5 (9.9% [95% CI: −6.3, 28.8] per 2,750 $cm^{-3}$and NC at lag 2−5 (5.8% [95% CI: −6.4, 19.7] per 3,675 cm^{-3}). No evidence of an association was observed with respiratory mortality and the other PM size fractions examined. Although some sensitivity analyses focusing on model specification were conducted based on the UFP—respiratory mortality association, the wide confidence intervals complicate the interpretation of these analyses.

While Lanzinger et al. (2016) focused on examining the lag structure of associations across different multiday lags, Stafoggia et al. (2017) focused on examining whether there was evidence of an association between short-term UFP exposure and mortality across a range of single-day lags (i.e., 0 to 10 days). Across the single-lag days examined, the authors reported evidence of positive associations with total (nonaccidental) mortality at lags 5 through 7 ranging from 0.32−0.37%, with associations largest in magnitude for respiratory (lag 6) and cardiovascular (lag 7) mortality also within this range, although there were wide confidence intervals (Figure 11-30). Subsequent copollutant and sensitivity analyses focused specifically on associations reported for lag 6, where single-pollutant models resulted in a 0.35% increase in total (nonaccidental) mortality (95% CI: −0.05, 0.75) for a 10,000 particle/cm^3 increase in 24-hour average NC.

The results from copollutant analyses indicate that associations with total (nonaccidental) mortality are relatively unchanged in models with CO (0.30%) and O_3 (0.27%), while there was some evidence of an attenuation in models with PM_{10} (0.22%). The authors reported no evidence of an association with NC in copollutant models with $PM_{2.5}$, $PM_{10-2.5}$, and NO_2, providing some evidence of potential confounding. Complicating the overall interpretation of results from Stafoggia et al. (2017) is that further analysis of the pooled results across cities identified that the positive association observed at lag 6 was largely driven by the city of Rome. As a result, when excluding Rome from the meta-analysis there was no evidence of an association between short-term NC exposure and total (nonaccidental) mortality.



Note: Natural = total (nonaccidental) mortality.

Figure 11-30 Percent increase in total (nonaccidental), cardiovascular, and respiratory mortality across eight European cities for a 10,000 particle/cm^3 increase in 24-hour average number concentration (NC) across lags 0 to 10 days.

11.5.3 Associations Between Short-Term UFP Exposure and Total Mortality in Single-City Studies

Recent single-city studies all examined a number of different size fractions of particles within the ultrafine range along with exposure metrics, as detailed in Table 11-13. In many cases the size fractions examined are a reflection of the monitor used. For example, some monitors that measure NC result in a larger size distribution being measured than others (Section 2.4.3). As a result, the NC metric is considered a proxy for UFP exposure due to the potential for particles larger than the traditional 100 nm cutoff for UFPs being included in the measurement (Section 2.4.3.1). Overall, the inconsistency in the size fractions examined across studies complicates the interpretation of results, but collectively can inform if there is evidence of a relationship between short-term UFP exposure and mortality.

The single-city studies conducted to date that examined short-term UFP exposure and mortality are limited to Europe and Asia. Samoli et al. (2016) in a study conducted in London, U.K. used a

traditional source apportionment method (i.e., positive matrix factorization) to identify UFP sources based on NC data. The source apportionment analyses identified four sources each with a different peak in the size distribution: urban background (30 nm), nucleation (70 nm), secondary (20 nm), and traffic (250 nm). In analyses focusing on total (nonaccidental) and cardiovascular mortality at lag 1 and respiratory mortality at lag 2, the authors reported no evidence of an association with total NC. When examining source-specific NC, a small positive association was observed for total (nonaccidental) mortality and nucleation and traffic sources (~0.20% increase), but confidence intervals are wide. There was no evidence of an association with any NC sources and cardiovascular mortality with evidence of a positive association between respiratory mortality and only the urban background source (1.4% increase [95% CI: −0.97, 3.89] for a 1,806 number/cm^3 increase). When measuring NC, although a large percentage of particles are <0.1 µm (see Section 2.4.3.1), the authors used two different types of monitors with different size ranges for the NC and source-specific NC analysis, resulting in some degree of uncertainty when comparing the NC and source-specific NC results.

The single-city studies conducted in China systematically examined various UFP size fractions and exposure metrics. Breitner et al. (2011) and Leitte et al. (2012) were both conducted in Beijing, China over the same study duration, but focused on different UFP size fractions and metrics as well as mortality outcomes. Both Breitner et al. (2011) and Leitte et al. (2012) examined some particle size ranges that are outside the scope of the UFP - mortality evaluation and are detailed in Section 11.1.9. Breitner et al. (2011) in a study focusing on cardiovascular-related mortality, in addition to focusing on NC, converted NC to SC, assuming spherical particles with constant density, and MC, assuming a density of 1.5 g/cm^3. For cardiovascular mortality, the authors observed positive associations, but with wide confidence intervals for all NC metrics at lag 0-4 days (see Table 11-13). Positive, but uncertain, associations were also observed for $SC_{0.1\text{-}0.3}$ and $MC_{0.1\text{-}0.3}$ at lag 0−4 days ($SC_{0.1–0.3}$: 0.24% [95% CI: −2.72, 3.29] per IQR [265.9 µ$m^2cm^{3–}$]; $MC_{0.1–0.3}$: 0.13% [95% CI: −2.87, 3.23] per IQR [14.0 µg/m^3]). When comparing the multiday lag results to single-day lags, there was variability in the magnitude and direction of the association across single-day lags across metrics, while the multiday average lag was consistently positive. A similar pattern of associations was observed for ischemic heart disease mortality. Copollutant models focused only on the Aitken mode particles and NC_1 at lag 2. Across the copollutant models, when including the other size fractions examined in the model ranging up to 1 µm, both Aitken mode particles (0.03−0.1 µm) and NC1 (<0.8 µm) associations were robust. Breitner et al. (2011) also examined whether the UFP associations were modified by specific types of air masses identified through cluster analysis. The authors did not observe any evidence that air mass origin modified NC associations, however, mortality associations at lag 2 for the SC and MC metrics were stronger for air masses representative of stagnant air masses and air masses originating from Southern China.

Unlike Breitner et al. (2011), Leitte et al. (2012) only focused on NC metrics and respiratory mortality. Across the different UFP size fractions, the authors reported consistent positive associations between respiratory mortality and NC for all particle fractions between 3 nm and 1 µm at lag 2, but confidence intervals were wide. Focusing on lag 0−3 days, the strongest association was observed for

NC_{total}, which was defined as particles ranging in size from 3 nm−1 µm where Leitte et al. (2012) reported an 8.9% (95%CI: −3.8, 23.3%) increase in respiratory mortality per IQR increase (14,000 cm^{3-}). In comparison, for UFP, which was defined as particles ranging in size from 3−100 nm, the authors observed a 3.9% (95%CI: −7.3, 16.4%) increase per IQR increase (13,000 cm^{3-}). When comparing the results from single-day lags to multiday averages (i.e., 0−4 and 0−5 days), the magnitude of the association between all of the size fractions, except the 30−50 nm size fraction, and respiratory mortality were larger in magnitude, but the confidence intervals were also larger compared to the single-day lag estimates. Whereas Breitner et al. (2011) only focused on copollutant models with other UFP size fractions, Leitte et al. (2012) examined gaseous pollutants, for NC_{total} and found associations remained relatively unchanged in models with NO_2 and SO_2 (Figure 11-31).

Leitte et al. (2012) also examined potential modification of the respiratory mortality and UFP relationship by different air masses, focusing on the NC_{total} fraction, and similar to the cardiovascular mortality results in Breitner et al. (2011) observed some evidence that particularly stagnant air masses as well as air masses originating from some areas of China may modify the NC_{total} association.

11.5.4 Summary and Causality Determination

Compared to the examination of other PM size fractions, a smaller number of studies have examined the association between short-term UFP exposure and total (nonaccidental) mortality. At the completion of the 2009 PM ISA, the overall body of evidence was limited and based on a few single-city studies that provided some evidence of positive associations, but at lags longer than those observed for other PM size fractions. Recent evidence from both multi- and single-city studies provides additional insight on the relationship between short-term UFP exposure and mortality, but the uncertainties and limitations in the evidence identified in the 2009 PM ISA remain, including, but not limited to: the metric

to examine UFP exposures (i.e., NC, SC, or MC); the size range to consider when examining UFP exposures; exposure measurement error due to the spatial and temporal variability in UFPs; and the correlation between UFPs and gaseous pollutants, which collectively continue to support that the evidence is inadequate to infer a causal relationship. Although there is evidence of positive associations for NC for different size fractions in a few studies, confidence intervals are often wide, and studies did not monitor and, subsequently examine, the same UFP size fractions complicating the interpretation of results across studies. Additionally, there is limited and inconsistent cardiovascular (Chapter 6) and respiratory (Chapter 5) morbidity evidence to provide biological plausibility to support the positive associations observed in some studies for total mortality. This section describes the evaluation of evidence for total (nonaccidental) mortality, with respect to the causality determination for short-term exposures to UFPs using the framework described in Table II of the Preamble to the ISAs (U.S. EPA, 2015b). The key evidence, as it relates to the causal framework, is summarized in Table 11-14.

Recent multi- and single-city studies that examined the association between short-term UFP exposure and total (nonaccidental) mortality provide inconsistent evidence of a positive association, which is further supported by studies that examined cardiovascular and respiratory mortality. The evaluation of the evidence from recent studies is complicated by the different UFP size fractions examined and exposure metrics used (i.e., NC, SC, and MC). Across studies, the majority primarily examined UFP associations using the NC metric, but the range of size fractions examined varied preventing a complete comparison of the pattern of associations across studies. Of the few studies that examined copollutant confounding, the focus was on examining associations with NC. In the assessment of copollutant confounding, the NC size fractions examined varied from focusing on a specific size fraction range (e.g., 0.03−0.1 μm) to total NC. The copollutant model results provided evidence that the NC associations were both robust and sensitive to adjustment depending on the PM size fraction and gaseous pollutant included in the model.

Across epidemiologic studies that examined short-term UFP exposure and mortality, an inherent limitation is the use of primarily one monitoring site to estimate exposure, which potentially contributes to exposure measurement error. The potential for exposure measurement error is reflected in the limited number of studies demonstrating greater spatial variability in UFP concentrations (i.e., NC) as well as changes in the particle size distribution at increasing distances from sources (Section 2.5.1.1.5, Section 2.5.1.2.4, Section 3.4.5) There is also limited information on the temporal variability in UFP concentrations (i.e., NC) over an urban area (Section 2.5.2.2.3).

Table 11-14 Summary of evidence that is inadequate to infer the presence or absence of a causal relationship between short-term UFP exposure and total mortality.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	UFP Concentrations Associated with Effects[c]
Inconsistent epidemiologic evidence from a limited number of studies at relevant UFP concentrations	Some evidence of positive, but imprecise, increases in mortality in multicity and single-city studies conducted in Europe and Asia, with no studies conducted in the U.S. Limited evidence of positive associations for cardiovascular and respiratory mortality in multi- and single-city studies conducted in Europe, and Asia, with no studies conducted in the U.S.	Section 11.5.2 Section 11.5.3 Table 11-13 Section 5.5.8 Section 6.5.8	24−h avg: NC: Variability in UFP size ranges examined prevents providing a range. SC (μm^2 cm^{-3}) 0.1–0.3 µm: 567.0 MC ($\mu g/m^3$) 0.1–0.3 µm: 27.8
Limited epidemiologic evidence from copollutant models for an independent UFP association	Some evidence that UFP associations using the NC metric are relatively unchanged with CO and O_3 and other NC size ranges, but potentially attenuated with $PM_{2.5}$, $PM_{10-2.5}$, and NO_2.	Section 11.5.2 Section 11.5.3	
Uncertainty regarding exposure metric and UFP size fraction	Inconsistency in the UFP metric used (i.e., NC, SC, and MC) and UFP size fraction examined complicating interpretation of results across studies.	Section 11.4.1	
Uncertainty regarding exposure measurement error	All studies relied on one monitor to measure UFPs, which is inadequate based on limited data demonstrating both that there is greater spatial variability in UFPs (i.e., NC) and that the particle size distribution changes with distance from source. Additionally, there is limited information on the temporal variability in UFP concentrations.	Section 2.5.1.1.5 Section 2.5.1.2.4 Section 2.5.2.2.3 Section 3.4.5 Table 11-13	
Limited and inconsistent evidence for biological plausibility from cardiovascular and respiratory morbidity	Limited evidence from studies examining short-term UFP exposure and respiratory and cardiovascular effects provide limited biological plausibility for a relationship between short-term UFP exposure and cardiovascular- and respiratory-related mortality.	Section 5.5 Section 6.7	

[a]Based on aspects considered in judgments of causality and weight of evidence in causal framework in Table I and Table II of the Preamble to the ISAs (U.S. EPA, 2015b).

[b]Describes the key evidence and references, supporting or contradicting, contributing most heavily to the causality determination and, where applicable, to uncertainties or inconsistencies. References to earlier sections indicate where full body of evidence is described.

[c]Describes the UFP concentrations and metric (i.e., number concentration [NC], surface area concentration [SC], mass concentration [MC]) with which the evidence is substantiated.

Overall, recent epidemiologic studies that examined short-term UFP exposure and mortality provide limited and inconsistent evidence of a positive association in both single and copollutant models. There is also limited evidence of biological plausibility from the assessment of short-term UFP exposures and respiratory and cardiovascular morbidity to support potential UFP-related mortality (Section 5.5, Section 6.7). Additionally, across studies there is a lack of consistency in terms of the UFP metric and size fractions examined, which complicate the interpretation of results, along with the potential for exposure measurement error due to uncertainty in the spatial and temporal variability in UFP concentrations. **Collectively, the epidemiologic evidence is inadequate to infer the presence or absence of a causal relationship between short-term UFP exposure and total mortality.**

11.6 Long-Term UFP Exposure and Total Mortality

The 2009 PM ISA reported that no epidemiologic studies evaluated the effects of long-term UFP exposure and mortality, concluding that the evidence was "inadequate to determine if a causal relationship exists between long-term UFP exposure and mortality." A recent study provides some additional evidence to inform the relationship between long-term UFP exposure and mortality, though the overall evidence base remains limited.

11.6.1 Biological Plausibility for Long-Term UFP Exposure and Total Mortality

The preceding chapters characterized evidence related to evaluating the biological plausibility by which long-term UFP exposure may lead to the morbidity effects that are the largest contributors to total (nonaccidental) mortality, specifically cardiovascular and respiratory morbidity (Section 6.6.1 and Section 5.6.1, respectively). This evidence is derived from animal toxicological, controlled human exposure, and epidemiologic studies. Section 6.6.1 outlines the available evidence for plausible mechanisms by which inhalation exposure to UFPs could result in initial events to endpoints relevant to the cardiovascular system. Similarly, Section 5.6.1 characterizes the available evidence by which inhalation exposure to UFPs could progress from initial events to endpoints relevant to the respiratory system. This evidence is limited to several experimental studies of oxidative stress and inflammatory changes that do not provide consistent evidence for initial events or progression along a plausible pathway from UFP exposure to respiratory health endpoints. Collectively, there is limited available evidence for cardiovascular and respiratory morbidity supporting potential biological pathways by which long-term UFP exposures could result in mortality.

11.6.2 Associations between Long-Term UFP Exposure and Total Mortality

In 2009, Hoek et al. (2009) published an expert elicitation in which 11 European experts in epidemiology, toxicology and clinical science were asked to quantify the relationship between UFP exposure and health endpoints, including mortality. The experts emphasized that the lack of studies examining long-term UFP exposure and mortality contributed greatly to the uncertainty of this relationship. The experts were asked to estimate the "percent change in annual, total (nonaccidental) mortality in the general EU [European Union] population resulting from a permanent 1,000 particles/cm^2 reduction in annual average UFP across Europe (given a population-weighted baseline concentration of 20,000 particles/cm^2)." While there was substantial variability, the median response from the experts was a 0.30% decrease in annual, total (nonaccidental) mortality, though none of the experts excluded the possibility that UFPs had no effect. In a recent study, Ostro et al. (2015) examined the association between UFP (<0.1 μm) mass concentrations and mortality among women in the California Teachers Cohort. The authors used a chemical transport model to predict UFP concentrations with a 4-km spatial resolution, observing a positive association with IHD mortality (HR: 1.10; 95% CI: 1.02, 1.18, per 0.969 μg/m^3 increase). Associations with total (nonaccidental), cardiovascular, and respiratory mortality were near the null value.

Overall, the literature base for long-term UFP exposure and mortality remains very small, with one study (Ostro et al., 2015) reporting results for UFP mass concentration. There are no studies that examine UFP number concentration. An expert elicitation conducted in Europe (Hoek et al., 2009) asked experts in epidemiology, toxicology and clinical sciences to review the available evidence for the health effects of UFPs. The experts concluded that long-term exposure could affect mortality risk, but due to the small literature base and associated uncertainties, they could not rule out the possibility of no UFP effect on mortality.

11.6.3 Summary and Causality Determination

This section describes the evaluation of evidence for total (nonaccidental) mortality, with respect to the causality determination for long-term exposures to UFPs using the framework described in Table II of the Preamble to the ISAs (U.S. EPA, 2015b). The key evidence, as it relates to the causal framework, is summarized in Table 11-15. Compared to the examination of other PM size fractions, a smaller number of studies have examined the association between long-term UFP exposure and total (nonaccidental) mortality. At the completion of the 2009 PM ISA, there were no available studies examining long-term UFP exposure and total mortality. Recent evidence from the CA Teachers cohort provides little insight on the relationship between long-term UFP exposure and mortality due to generally null associations and the uncertainties and limitations in the evidence base. Additionally, there is limited and inconsistent cardiovascular (Chapter 6) and respiratory (Chapter 5) morbidity evidence to provide biological

plausibility to support an association between UFPs and total mortality. **Overall, the evidence is inadequate to infer the presence or absence of a causal relationship between long-term UFP exposure and total mortality.**

Table 11-15 Summary of evidence that is inadequate to infer the presence or absence of a causal relationship between long-term UFP exposure and total mortality.

Rationale for Causality Determination[a]	Key Evidence[b]	Key References[b]	$PM_{2.5}$ Concentrations Associated with Effects[c]
Limited and inconsistent epidemiologic evidence	Single study observes generally null association with total mortality	Ostro et al. (2015)	1,293 ng/m^3
Uncertainty regarding potential confounding by copollutants	No studies examine potential confounding of UFP associations by copollutants	Section 11.6.2	
Uncertainty regarding exposure measurement error	Chemical transport model to predict UFP concentrations with a 4-km spatial resolution	Ostro et al. (2015)	
Uncertainty regarding biological plausibility	Little evidence for long-term UFP exposure and cardiovascular or respiratory morbidity	Section 5.6 and Section 6.7	

UFP = ultrafine particle.

CHAPTER 12 POPULATIONS AND LIFESTAGES POTENTIALLY AT INCREASED RISK OF A PARTICULATE MATTER-RELATED HEALTH EFFECT

Summary of Populations and Lifestages Potentially at Increased Risk of a Particulate Matter-Related Health Effect

- The preceding health effects chapters in this ISA characterized a large body of evidence examining $PM_{2.5}$-related health effects and demonstrate that there is strong evidence for a range of health effects due to short- and long-term $PM_{2.5}$ exposures that are observed in both the general population as well as specific populations (e.g., people with a pre-existing disease) and lifestages (i.e., children and older adults). ***Thus, extensive evidence in the health effects chapters indicates that both the general population as well as specific populations and lifestages are at risk for $PM_{2.5}$-related health effects.***
- More specific consideration is often given to specific lifestages and populations, such as children, those with pre-existing diseases, or certain sociodemographic characteristic (e.g., low socioeconomic status) to determine if these unique populations and lifestages might be at increased risk of an air pollutant-related health effect relative to others in the population that do not have that characteristic.
- While preceding chapters focus on whether there is evidence broadly of $PM_{2.5}$-related health effects, the objective of this chapter is to evaluate the extent to which the evidence indicates that a population or lifestage is at **disproportionately greater risk,** using an established framework to assess the available evidence. ***Thus, this chapter is addressing the specific question: are specific populations or lifestages at increased risk of a $PM_{2.5}$-related health effect compared to a reference population?***
- In addressing this question, the evaluation builds on evidence from the 2009 PM ISA and takes into consideration a broad range of recent evidence from epidemiologic, controlled human exposure, and animal toxicological studies, in addition to information on differential exposure or dosimetry. Conclusions are drawn based on an integrated evaluation of evidence in the context of the framework.

12.1 Introduction

The NAAQS are intended to protect public health with an adequate margin of safety, which includes protection for the population as a whole and for those groups potentially at increased risk for health effects in response to exposure to a criteria air pollutant (e.g., PM) [see Preamble to the ISA (U.S. EPA, 2015b)]. There is interindividual variation in both physiological responses, as well as exposures to ambient air pollution. A variety of terms have been used in the scientific literature to describe risk factors and subsequently populations or lifestages that may be at increased risk of an air pollutant-related health effect, including susceptible, vulnerable, sensitive, at risk, and response-modifying factor (Vinikoor-Imler

et al., 2014) [see Preamble to the ISA (U.S. EPA, 2015b)]. Acknowledging the inconsistency in definitions for these terms across the scientific literature and the lack of a consensus on terminology in the scientific community, "at-risk is the all-encompassing term used within this chapter for groups with specific factors that increase the risk of an air pollutant (e.g., PM)-related health effect in a population", as initially detailed in the 2013 O_3 ISA (U.S. EPA, 2013b). Therefore, while there is strong evidence for health effects to occur in the exposed general population and in some specific populations or lifestages, this chapter focuses on the evaluation and characterization of evidence informing if there are populations or lifestages potentially at increased risk of a PM-related health effect with specific emphasis on studies that compare responses to a reference population, where appropriate [see Preamble to the ISA (U.S. EPA, 2015b)].

As discussed in the Preamble to the ISAs (U.S. EPA, 2015b), the risk of health effects from exposure to an ambient air pollutant, including PM, may be modified as a result of intrinsic (e.g., pre-existing disease, genetic factors) or extrinsic factors (e.g., sociodemographic or behavioral factors), differences in internal dose (e.g., due to variability in ventilation rates or exercise behaviors), or differences in exposure to air pollutant concentrations (e.g., more time spent in areas with higher ambient concentrations). For the purposes of informing decisions on the NAAQS, the focus of this chapter is on identifying those populations or lifestages at increased risk of a PM-related health effect. It is recognized that, in many cases, subsets of the population are at increased risk of a PM-related health effect due to a combination or co-occurrence of factors [e.g., residential location and socioeconomic status (SES)], but evidence on the interaction among factors remains very limited. Thus, the following sections identify, evaluate, and characterize the overall confidence that individual factors potentially result in increased risk for PM-related health effects [see Preamble to the ISAs (U.S. EPA, 2015b)].

The preceding chapters of this ISA focus on assessing whether exposure to PM of various size fractions is causally related to health effects regardless of population or lifestage. It is the collective body of evidence spanning populations and lifestages that ultimately forms the basis of the causality determinations detailed within each of the health chapters. These chapters clearly conclude that there is a large body of evidence that demonstrates health effects with PM, particularly $PM_{2.5}$, across populations with diverse characteristics (e.g., children, older adults, people with a pre-existing cardiovascular disease, etc.). While the health chapters assess the degree to which there is evidence of a causal relationship between PM exposure and health effects, this chapter is focusing solely on the question: ***Are there specific populations and lifestages at increased risk of a PM-related health effect compared to a reference population?***

This analysis is one aspect to be considered in the latter evaluation of the extent to which the NAAQS provide public health protection with an adequate margin of safety.

12.2 Approach to Evaluating and Characterizing the Evidence for Populations or Lifestages Potentially at Increased Risk

The systematic approach used to identify, evaluate, and characterize evidence for factors that may increase the risk of a population or specific lifestage to an air pollutant-related health effect, including PM, is described in more detail in the Preamble (U.S. EPA, 2015b). The evidence evaluated in this chapter includes relevant studies discussed in Chapters 5-11 of this ISA relevant to the evaluation of populations and lifestages potentially at increased risk of a PM-related health effect and builds on the evidence presented in the 2009 PM ISA (U.S. EPA, 2009). The evaluation of the evidence focuses on those health outcomes and size fractions of PM for which a "*causal*" or "*likely to be a causal*" relationship was concluded in Chapters 5-11 of this ISA with additional supporting evidence from studies of health outcomes for which the causality determination is "suggestive" or "inadequate". More specifically, this chapter focuses on the health effects related to $PM_{2.5}$ based on the strength of the evidence as described in the health chapters. In addition, focus is given to the endpoints (e.g., mortality, asthma exacerbation, lung development, etc.) that formed the basis of the conclusions. In addition, it is important to recognize that the 2009 PM ISA (U.S. EPA, 2015b) focused broadly on the extent to which evidence indicated that certain populations or lifestages were "susceptible" to a PM-related health effect, regardless of size fraction. As part of the 2013 O_3 ISA (U.S. EPA, 2013a), a framework was developed to systematically evaluate the collective body of evidence and inform whether a specific population or lifestage is at increased risk for an air pollutant-related health effect compared to a reference population, where applicable[82]. As such, it is important to note that the conclusions detailed within this ISA are more nuanced than the dichotomous conclusions of whether a population or lifestage is susceptible for a PM-related health effect as reflected in the 2009 PM ISA (U.S. EPA, 2009).

As described in the Preamble and the PM IRP and demonstrated in previous ISAs (U.S. EPA, 2017, 2016a, b, 2015a, 2013a, b), evidence is integrated across scientific disciplines (i.e., epidemiology, controlled human exposure, and animal toxicology) and health effects, and when available, with relevant dosimetric information (Chapter 4) as well as exposure differences (Chapter 3) in the evaluation process. Epidemiologic studies that include stratified analyses to compare populations or lifestages exposed to similar $PM_{2.5}$ concentrations within the same study design directly inform the question of disproportionate risk. A more detailed presentation of this evidence is included in a supplement to this chapter (U.S. EPA, 2018). Other epidemiologic studies that do not stratify results but instead examine a specific population or lifestage can provide further evidence of increased risk particularly when a health effect is only relevant for a unique population or lifestage (e.g., lung function development in children). When evaluating results

[82] In some cases, studies do not include a reference population for comparison because there are outcomes that are only relevant to some specific populations and lifestages. For example, lung function development is only examined in studies of children because this outcome cannot be measured in adults as lung development is already complete. Another example is studies of asthma hospitalization or emergency department visits, where studies often examine these events only for the population with asthma because those without asthma would not have an asthma exacerbation.

across epidemiologic studies, similar to the characterization of epidemiologic evidence in Chapters 5-11, statistical significance is not the sole criterion by which effect modification and evidence of increased risk is determined; emphasis is placed on patterns or trends in results across these epidemiologic studies.[83] Experimental studies in human subjects or animal models that focus on factors, such as genetic background or health status (e.g., pre-existing asthma), are also important lines of evidence to evaluate to establish coherence of effects across disciplines. These studies can also inform the independent effects of PM as well as biological plausibility of effects observed in epidemiologic studies. Additionally, dosimetry studies can further inform biological plausibility by demonstrating whether the deposition of PM within the body might vary in a particular population or lifestage. Differential exposure to PM in populations and lifestages is also considered when available, though these types of evidence tend to be sparser.

As stated, the objective of this chapter is to identify, evaluate, and characterize the extent to which various factors may increase the risk of a PM-related health effect in a population or lifestage compared to a reference population, where applicable, building on the conclusions drawn in previous chapters in the ISA. More specifically, Table 12-1 presents the framework applied to the available evidence in drawing conclusions on increased risk. The broad categories of factors evaluated include pre-existing disease (Section 12.3), genetic background (Section 12.4), sociodemographic factors (Section 12.5), and behavioral and other factors (see Section 12.6). Furthermore, factors that are considered in this chapter are not predetermined, but are included based on the availability of evidence in the scientific literature. The classifications of evidence are characterized in Table 12-1. A summary of the characterization of the evidence for each factor considered within this chapter is presented in Section 12.7.

It is important to note that while a broad range of evidence is evaluated, there are uncertainties and limitations inherent in the approach used within this chapter to identify populations or lifestages potentially at disproportionately increased risk of a PM-related health effect. First, publication bias, or the tendency not to report quantitatively null results in epidemiologic studies is more frequent in stratified results than main effects, and this can introduce uncertainty when evaluating increased risk or risk modification in general. However, in the evaluation and characterization of the evidence within this chapter, where the evidence is considered "adequate" to classify a group as being at increased risk (Table 12-1) even when considering the strengths and limitations, the collective body of evidence is strong enough to outweigh this uncertainty. In addition, there is variability in the indicators or metrics used to define the populations and/or lifestages that are examined, which can be an important limitation (e.g., well-controlled vs. uncontrolled pre-existing disease, body mass index, indicators of socioeconomic status, various age ranges). Another aspect to consider is variability within the populations or lifestages, such as behavioral differences, biological differences (e.g. obese vs. non-obese), and adherence to treatment for pre-existing disease). These limitations and uncertainties can impact the extent to which the

[83] As detailed in the Preface, risk estimates are for a 10 $\mu g/m^3$ increase in 24-hour avg $PM_{2.5}$ concentrations or a 5 $\mu g/m^3$ increase in annual $PM_{2.5}$ concentrations, unless otherwise noted.

evidence can reliably indicate whether there is disproportionate risk in a population or lifestage compared to a reference population and is considered where relevant.

Table 12-1 Characterization of evidence for factors potentially increasing the risk for particulate matter-related health effects.

Classification	Health Effects
Adequate evidence	There is substantial, consistent evidence within a discipline to conclude that a factor results in a population or lifestage being at increased risk of air pollutant-related health effect(s) relative to some reference population or lifestage. Where applicable, this evidence includes coherence across disciplines. Evidence includes multiple high-quality studies.
Suggestive evidence	The collective evidence suggests that a factor results in a population or lifestage being at increased risk of air pollutant-related health effect(s) relative to some reference population or lifestage, but the evidence is limited due to some inconsistency within a discipline or, where applicable, a lack of coherence across disciplines.
Inadequate evidence	The collective evidence is inadequate to determine whether a factor results in a population or lifestage being at increased risk of air pollutant-related health effect(s) relative to some reference population or lifestage. The available studies are of insufficient quantity, quality, consistency, and/or statistical power to permit a conclusion to be drawn.
Evidence of no effect	There is substantial, consistent evidence within a discipline to conclude that a factor does not result in a population or lifestage being at increased risk of air pollutant-related health effect(s) relative to some reference population or lifestage. Where applicable, the evidence includes coherence across disciplines. Evidence includes multiple high-quality studies.

12.3 Pre-Existing Diseases/Conditions

Individuals with pre-existing disease may be considered at greater risk of an air pollution-related health effect than those without disease because they are likely in a compromised biological state that can vary depending on the disease and severity. The 2009 PM ISA (U.S. EPA, 2009) concluded that those with pre-existing cardiovascular (CV) and respiratory diseases are generally more susceptible to the health effects associated with exposure to PM, but that evidence for diabetes and obesity was limited. Of the recent epidemiologic studies evaluating effect measure modification by pre-existing disease or condition, most focused on pre-existing CV disease (Section 12.3.1), pre-existing diabetes and metabolic syndrome (Section 12.3.2), obesity (Section 12.3.3), elevated cholesterol (Section 12.3.4), and pre-existing respiratory disease (Section 12.3.5). Table 12-2 presents the prevalence of these diseases from the National Health Interview Survey conducted by the Centers for Disease Control and Prevention's (CDC's) National Center for Health Statistics (Blackwell and Villarroel, 2018), including the proportion of adults with a current diagnosis categorized by age and geographic region. The large proportions of the U.S. population affected by many chronic diseases, including various cardiovascular diseases, indicates

the potential public health impact, and thus, the importance of characterizing if certain subpopulations may be at increased risk for $PM_{2.5}$-related health effects.

Table 12-2 Prevalence of cardiovascular diseases, diabetes, obesity, and respiratory diseases among adults by age and region in the U.S. in 2016.

	Adults (18+)	Age (%)[a]				Region (%)[b]			
Chronic Disease/Condition	N (in thousands)	18−44	45−64	65−74	75+	North east	Midwest	South	West
All (N, in thousands)	245,142	113,401	83,703	28, 532	19,507	44,851	54,359	87,402	58,531
Selected cardiovascular diseases/conditions									
All heart disease	28,064	3.8	12.2	22.6	36.5	10.2	11.8	11.0	9.4
Coronary heart disease	15,230	1.2	6.0	13.9	25.1	5.4	6.4	6.3	4.5
Hypertension	66,443	9.2	34.4	55.7	59.1	23.5	26.0	27.0	21.9
Stroke	7,449	0.6	3.2	6.6	11.1	2.4	2.5	3.2	2.8
Metabolic disorders/conditions									
Diabetes	23,104	2.8	12.5	23.0	19.4	8.5	9.3	9.3	7.9
Obesity (BMI ≥30 kg/m^2)	70,723	27.5	34.7	31.5	21.2	25.9	33.4	32.1	24.6
Overweight (BMI 25−30 kg/m^2)	82,870	31.8	36.9	40.5	38.3	35.8	33.1	34.2	35.8
Selected respiratory diseases									
Asthmatic	20,383	8.1	9.2	8.3	6.0	9.4	9.0	7.3	8.3
COPD—chronic bronchitis	8,940	2.0	5.0	5.3	4.9	3.1	3.7	4.0	2.6
COPD—emphysema	3,524	0.2	1.8	3.6	4.0	1.2	1.5	1.4	0.9

BMI = body mass index; COPD = chronic obstructive pulmonary disease.

[a]Percentage of individual adults within each age group with disease, based on N (at the top of each age column).

[b]Percentage of individual adults (18+) within each geographic region with disease, based on N (at the top of each region column).

[c]Asthma prevalence is reported for "still has asthma."

12.3.1 Cardiovascular Disease

Overview

- Approximately 12% of adults in the U.S. have a CV disease, and CV disease is the leading cause of death in the U.S, accounting for one in four deaths.
- A limited number of epidemiologic studies included in the current and previous ISAs have conducted stratified analyses; while they do not clearly demonstrate increased risk across all pre-existing CV diseases. There is some evidence that those with hypertension are at increased risk for $PM_{2.5}$-related health effects compared to those without hypertension, but there are inconsistencies.
- Strong evidence demonstrates that there is a causal relationship between CV effects and short- and long-term exposures to $PM_{2.5}$. Some of the evidence is from studies of panels or cohorts with pre-existing CV disease, which provide supporting evidence but do not directly inform an increase in risk.
- **Overall, the evidence is suggestive that those with pre-existing CV disease, particularly hypertension, may be at increased risk for $PM_{2.5}$ related health effects compared to those without a pre-existing CV disease.**

Cardiovascular disease is the primary cause of death in the U.S., and approximately 12% of adults report a diagnosis of heart disease [Table 12-2; (Blackwell and Villarroel, 2018)]. While evidence demonstrates that a causal relationship exists between short- and long-term $PM_{2.5}$ exposure and cardiovascular effects based on recent evidence, building from studies evaluated in the 2009 PM ISA (U.S. EPA, 2009), evidence addressing whether or not individuals with pre-existing cardiovascular disease are at increased risk for $PM_{2.5}$-associated health effects compared to those without pre-existing CV disease is complex. The evidence examining differential risk for $PM_{2.5}$-related health effects in individuals with pre-existing cardiovascular disease in the 2009 PM ISA (U.S. EPA, 2009) was limited and inconsistent, though studies from the recent literature provide some additional evidence that pre-existing cardiovascular disease may modify the risk of $PM_{2.5}$ for cardiovascular outcomes.

As described in Chapter 6, both previous evidence from the 2009 PM ISA (U.S. EPA, 2009) and recent evidence demonstrate that there is a causal relationship between short- and long-term $PM_{2.5}$ exposure and cardiovascular effects. Both conclusions were informed by evidence for $PM_{2.5}$-related mortality, and hospital admissions and emergency department visits for IHD associated with short-term exposures to $PM_{2.5}$. It is well-recognized that these serious population-level effects are preceded by altered cardiovascular function, though there are no studies that examine differential risk for these serious effects in individuals with and without underlying cardiovascular conditions or diseases. There is, however, evidence from studies examining these serious health effects in only adults with pre-existing cardiovascular disease that demonstrate that $PM_{2.5}$-associated CV effects are observed in this population (Chapter 6). Thus, while this evidence does not inform if those with pre-existing CV disease are at increased risk for a $PM_{2.5}$-related health effect compared to those without pre-existing CV disease, it does indicate that these individuals are at-risk.

Recent studies examining whether there is evidence of increased risk for $PM_{2.5}$-related health effects in people with pre-existing cardiovascular disease have considered an array of specific cardiovascular diseases/conditions (Supplemental Table S12-1) (U.S. EPA, 2018). As was the case for the 2009 PM ISA, hypertension is the most commonly examined cardiovascular disease in epidemiologic studies that conducted stratified analyses. Puett et al. (2009) and Goldberg et al. (2013) both reported positive associations between long-term $PM_{2.5}$ exposure and mortality in the Nurses' Health Study and among older adults in Montreal, Canada, respectively. However, Puett et al. (2009) did not find associations to differ consistently by hypertension status; only associations with fatal CHD, and not mortality or first CHD, were increased for those with hypertension compared to those without. Other studies examining $PM_{2.5}$-related ischemic stroke and incident diabetes also did not find evidence for increased risk among those with hypertension with short-term exposures (Wellenius et al., 2012a; O'Donnell et al., 2011) or long-term exposure (Hansen et al., 2016) (Chen et al., 2013). However, studies examining effect modification for $PM_{2.5}$-associated changes in subclinical CVD outcomes (e.g., blood pressure, inflammation, endothelial dysfunction) provide some evidence that effects in those with hypertension are larger with $PM_{2.5}$ exposure. Both Auchincloss et al. (2008) and Krishnan et al. (2012) conducted analyses within the MESA cohort and observed positive associations for pulse pressure, BAD, and FMD with long-term $PM_{2.5}$ exposure; associations were larger for study participants with hypertension, with the exception of BAD. Wellenius et al. (2013) also found in a study of community-dwelling older adults in Boston that those with hypertension had greater $PM_{2.5}$-related increases in flow velocity and cerebrovascular resistance, measures related to stroke and neurological conditions, with long-term exposure. Interleukin-6 and C-reactive protein, markers of inflammation, were also more strongly associated with long-term exposure to $PM_{2.5}$ in those with hypertension compared to those without (Hajat et al., 2015; Ostro et al., 2014).

Beyond hypertension, recent studies have also evaluated whether there is evidence that people with pre-existing coronary heart disease (CHD) are at increased risk of a PM-related health effect compared to those without CHD. However, all studies are from a single panel of adults from the Heinz Nixdorf Recall study. More specifically, participants in this panel ranged from 45−75 years of age and were from Ruhr area, Germany. Hennig et al. (2014), Viehmann et al. (2015), Hoffmann et al. (2009a), and Fuks et al. (2011) observed positive associations between 12-month $PM_{2.5}$ exposures and CRP, fibrinogen, and BP. When examining effect measure modification by CHD status, only Viehmann et al. (2015) found larger effects in those with CHD compared to those without. Hertel et al. (2010) also examined associations for CRP, and while positive associations across averaging times were observed, effect measure modification by CHD was not clear results varied for 2-day up to 28-day averages of $PM_{2.5}$.

Studies examining effect modification by pre-existing CV diseases other than hypertension or CHD are sparse and vary across outcomes making it difficult to draw conclusions. In addition to the differences across studies in the outcomes and populations examined, results across these studies are inconsistent and do not suggest that individuals with pre-existing CV disease, at a broad level, are at

increased risk for health effects related to short- or long-term exposures to $PM_{2.5}$. However, there is some evidence that those with hypertension, specifically, may be at increased risk compared to those without hypertension.

Evidence from controlled human exposure and animal toxicological studies evaluating whether or no pre-existing CV disease increases risk for $PM_{2.5}$-associated health effects is limited. A single CHE study from the recent literature is available that examined whether use of a respiratory filter could attenuate the cardiovascular effects of acute diesel exhaust (DE) exposure in patients with heart failure (HF) or healthy individuals (Vieira et al., 2016). BP was not significantly changed with DE exposure compared to air controls. When the FILTER-HF patients and healthy controls exercised for 6 minutes, BP increased with exercise in both groups but there were no statistically significant differences with DE exposure with or without filtration and results were similar in those with and without HF. No differences in HRV, HR, endothelial dysfunction, or arterial stiffness were observed for those with or without HF. In addition, the 2009 PM ISA(U.S. EPA, 2009) characterized evidence from studies that evaluated pulmonary outcomes in spontaneously hypertensive rats. These studies found some evidence for pulmonary inflammation following 4-hour to 3-day exposures to CAPs from RTP, NC; various sites in the Netherlands; a high-traffic area in Taiwan, and Detroit (Rohr et al., 2010; Campen et al., 2006; Cassee et al., 2005; Kodavanti et al., 2005; Lei et al., 2004) but lack of a comparison to a normotensive strain limits the utility of these studies in informing differential effects for pre-existing CV disease.

Taken together, the collective evidence is suggestive that individuals with pre-existing CV disease are at increased risk for $PM_{2.5}$-associated health effects compared to those without pre-existing CV disease. The evidence from epidemiologic studies conducting stratified analyses, controlled human exposure, and animal toxicological studies is not clear in describing increased risk across all pre-existing CV disease, but evidence for those with hypertension demonstrates a potential for increased risk. In addition, there is strong evidence described in Chapter 6 supporting a causal relationship between short-term $PM_{2.5}$ exposure and CV effects, based primarily on evidence for ischemic heart disease. As noted, the pathophysiology underlying the serious CV outcomes associated with $PM_{2.5}$ exposure is linked to a variety of underlying CV conditions, though they may be asymptomatic and undiagnosed. This uncertainty in disease diagnoses, and in addition, the variability in disease status complicate the examination of increased risk in these populations.

12.3.2 Pre-existing Diabetes and Metabolic Syndrome

Overview

- Diabetes mellitus is an important component of metabolic syndrome, as well as a risk factor for cardiovascular disease.
- In the 2009 PM ISA, there was limited evidence comparing $PM_{2.5}$-associated health effects in individuals with and without diabetes.
- Recent stratified epidemiologic analyses of short- and long-term $PM_{2.5}$ exposure do not consistently demonstrate increased risk among those with diabetes.
- **Overall, the evidence is inadequate to determine whether individuals with pre-existing diabetes are at increased risk for $PM_{2.5}$-related health effects compared to individuals without diabetes.**

Diabetes mellitus is a group of diseases characterized by high blood glucose levels and affects an estimated 30 million Americans, or 8.8% of the adult population, in 2016 (Blackwell and Villarroel, 2018). In addition, 84 million Americans are estimated to be living with prediabetes, a condition characterized by elevated fasting plasma glucose levels that is also a key risk factor for cardiovascular disease and a component of metabolic syndrome (CDC, 2017). As described in Chapter 7 (Section 7.2.2) metabolic syndrome components (i.e., fasting blood glucose, high blood pressure, dyslipidemia, and obesity) often co-occur and can contribute to atherosclerotic plaque progression causing damage to the vascular system and potentially promoting cardiovascular disease and heart failure. Furthermore, studies have demonstrated cardiovascular and metabolic effects in humans or animal models of diabetes as characterized in Chapter 6 and 7. It is conceivable that biological effects in individuals with diabetes may be further exacerbated by exposures to $PM_{2.5}$. Thus, this section characterizes the evidence informing if individuals with pre-existing metabolic disease, including diabetes, are at increased risk for $PM_{2.5}$-related health effects compared to the individuals without metabolic disease or diabetes.

The 2009 PM ISA (U.S. EPA, 2009) concluded there was some evidence suggesting increased PM-related health effects among those with diabetes; however, much of the evidence was inconsistent across several studies of hospital admission and emergency department visits and short-term PM_{10} exposure, with only one study evaluating the effects of $PM_{2.5}$ (Goldberg et al., 2006). Controlled human exposure and toxicological studies found limited evidence of differences in biomarkers by diabetes status, though the 2009 PM ISA (U.S. EPA, 2009) noted that it was unclear how differences in biomarker responses contribute to overall potential for cardiovascular risk in those with diabetes compared to those without diabetes. Recent epidemiologic and toxicological studies have focused on differential $PM_{2.5}$-related health effects for diabetes status and provide some evidence of increased risk, but there are inconsistencies in results across studies of mortality and cardiovascular outcomes (Supplemental Table S12-2) (U.S. EPA, 2018).

Several studies examined whether diabetes status modified associations between mortality and long-term $PM_{2.5}$ exposure. There was little evidence that $PM_{2.5}$-associated mortality was modified by diabetes status for long- or short-term $PM_{2.5}$ exposure across studies. Several multistate or statewide U.S. based studies of long-term $PM_{2.5}$ exposure reported slight variations in associations, though estimates were generally imprecise (i.e., wide 95% confidence intervals) and changes in risk were small (Wang et al., 2016b; Pope et al., 2014; Puett et al., 2009). One exception was a study of seven southeastern U.S. states, where Wang et al. (2017) observed an increase in risk for mortality associated with long-term $PM_{2.5}$ exposure among Medicare patients who also had a history of diabetes hospital admission compared to those that did not. Furthermore, this modification persisted across simultaneous stratifications of sex and race combinations. Too few studies were available to compare if there were differences by mortality cause. Among studies of short-term $PM_{2.5}$ exposure and mortality, only Goldberg et al. (2013) examined differential risk for $PM_{2.5}$-related mortality by diabetes status. This study demonstrated a slight increase in risk for nonaccidental mortality for cases with diabetes compared to all cases.

A number of studies also examined effect measure modification by diabetes status across an array of cardiovascular outcomes and long-term $PM_{2.5}$ exposure. Studies of incident hypertension and self-reported heart disease found little evidence for differences between individuals with or without diabetes (Hoffmann et al., 2009b; Johnson and Parker, 2009). Chan et al. (2015) and Fuks et al. (2011) observed larger $PM_{2.5}$-related decreases in blood pressure in those with diabetes; however, these differences were modest and imprecise (i.e., wide 95% confidence intervals). In contrast, in a study of the of the Nurses' Health Study cohort by Hart et al. (2015) examining incident CVD among women positive associations were observed for those with diabetes (HR: 1.44, 95% CI: 1.23, 1.68) compared to those without diabetes (HR: 0.94, 95% CI: 0.86, 1.03). Additionally, in a multicity study, Chen et al. (2014) observed a 41% increase in risk of incident hypertension among those with diabetes compared to those without; however, effect estimates were imprecise.

Among evaluations of short-term $PM_{2.5}$ exposure, some studies demonstrated higher risk of cardiovascular effects among individuals with diabetes compared to those without diabetes; while other studies did not observe changes in association based on diabetes status. Across studies, there is limited evidence of differential risk for changes in blood pressure (Wellenius et al., 2012b), heart failure (Haley et al., 2009), or transmural infarctions (Rich et al., 2010). One exception is a multicity study of ischemic stroke hospital admissions as determined by registry data in Ontario, Canada, which reported a positive association among those with diabetes, but observed little evidence of an association among those without diabetes (O'Donnell et al., 2011). Additionally, a panel study in Boston, MA observed little evidence of changes in blood pressure for individuals with well-controlled diabetes compared to a positive change in blood pressure among individuals with poorly controlled diabetes (Hoffmann et al., 2012), which indicates the potential for severity and control of diabetes to be an important factor beyond the presence or absence of the disease.

Several recent epidemiologic studies evaluated cardiovascular effects and measures of inflammation related to atherosclerosis in individuals exposed to PM and found larger, though imprecise, associations in participants with diabetes compared to those without. In a study of the MESA cohort, Allen et al. (2009) observed positive associations between $PM_{2.5}$ levels (2 year average) and elevated risk for calcification among individuals with diabetes. Furthermore, in those diabetic individuals with some or no calcification there was a positive change in the Agatston Score (a metric for coronary artery calcification). In other studies of the MESA cohort, Roux et al. (2008) observed no differences in associations between 20 year $PM_{2.5}$ averages and health measures of atherosclerosis by diabetes status. Additionally, Roux et al. (2008) and Van Hee et al. (2011) did not observe effect measure modification for $PM_{2.5}$-associated changes in QT-prolongation or ventricular conduction delay by diabetes status. In a German population-based cohort study (Heinz Nixdorf Recall study), Bauer et al. (2010) found a slightly weaker association between $PM_{2.5}$ exposure and carotid intima-media thickness (CIMT) for those with diabetes compared to those without.

Other studies specifically evaluated effect measure modification of associations between long- and short-term $PM_{2.5}$ exposure and markers of inflammation and coagulation (e.g., IL-6, CRP, and fibrinogen) by diabetes status. Specifically, in a study of 6 U.S. cities, Ostro et al. (2014) found the association between CRP and long-term $PM_{2.5}$ exposure to be modified by diabetes, with particularly large increases in CRP when comparing diabetes status among older adults. In contrast, Hoffmann et al. (2009a) conducted stratified analyses of the German Heinz Nixdorf Recall Study and found no distinct effect by diabetes status on PM associations with fibrinogen or CRP. In a study of short-term $PM_{2.5}$ exposure using the same German population-based cohort, Hertel et al. (2010) observed no distinct effect by diabetes status on the PM association with CRP.

Overall, evidence is inadequate to determine whether individuals with pre-existing diabetes are at increased risk for $PM_{2.5}$-associated health effects compared to those without diabetes. A number of recent studies provide inconsistent evidence for increased risk across a range of health effects associated with exposure to $PM_{2.5}$. Epidemiologic studies of diabetes predominantly evaluated associations between mortality and cardiovascular outcomes and long-term $PM_{2.5}$ exposure. Several studies reported elevated risk among those with diabetes; however, results were inconsistent within and across health outcomes. One important limitation for many studies was the small proportion of participants with diabetes, contributing to imprecise effect estimates (i.e., wide 95% confidence intervals). Additionally, as observed by Hoffmann et al. (2012), there may differences in response to PM exposure between those with well-controlled versus poorly controlled diabetes; however, few studies include this level of detail. Interpretation of the evidence is further complicated by the lack of information on individuals with prediabetes, which may exhibit similar underlying metabolic characteristics as those with diabetes. Relying solely on a clinical diagnosis may underestimate the population at increased risk and potentially introduce bias by similarly grouping those in a healthy metabolic state with those in a prediabetic metabolic state.

12.3.3 Obesity

Overview

- Obesity affects nearly a third of adults in the U.S. and is associated with low-grade inflammation that potentially interact with PM-related inflammation.
- Evidence indicates the potential for dosimetric differences for $PM_{2.5}$ among adults and children by obesity status.
- Evidence from recent stratified epidemiologic analyses of long-term $PM_{2.5}$ exposure and mortality suggest increased risk for those who are obese compared to those who are not; evidence for other outcomes is inconsistent.
- Variability in the definition of obesity limits comparability between studies and the ability to distinguish risk between those who are overweight and obese.
- **Overall, the evidence is suggestive of increased risk for $PM_{2.5}$-related health effects among those who are obese compared to those who are not.**

In the U.S., obesity is defined as a BMI of 30 kg/m^2 or greater, with a BMI between 25 and 30 kg/m^2 indicating an overweight individual. It is a public health issue of growing importance as obesity rates in adults have continually increased over several decades in the U.S., reaching an estimated 30% in 2016 (Blackwell and Villarroel, 2018). Furthermore, 36% of adults in the U.S. are considered overweight while 34% are at a healthy weight (BMI 18.5−25 kg/m^2) (Blackwell and Villarroel, 2018). Obesity or high BMI could potentially increase the risk of PM related health effects through multiple mechanisms. For example, persistent low grade inflammation associated with obesity or excess nutrients and energy (CN and AR, 2011; Gregor and Hotamisligil, 2011; Lumeng and Saltiel, 2011) may work in conjunction with PM related inflammation that is thought to facilitate atherosclerotic plaque progression (Section 6.3.1, Figure 6-11). Obesity is closely related to diabetes, and is one component of metabolic syndrome, where co-occurring factors may also be associated with PM exposure (Section 7.2.1, Figure 7-2) and further facilitate cardiovascular risk (Section 6.3.1). Nutritional access and poor diet (Section 12.6.2) may also be potential risk factors that act in combination with obesity. Additionally, those who are obese may experience greater particle deposition in the lung as there is evidence of increased ventilation rates for overweight or obese adults and children, as well as a lower nasal breathing fraction and increase deposition fraction among obese children (Section 4.1.3, Section 4.2.4.4).

The 2009 PM ISA evaluated several studies that reported differences in subclinical cardiovascular and inflammatory markers between obese and nonobese participants in association with short-term exposure to $PM_{2.5}$(Dubowsky et al., 2006; Schwartz et al., 2005; Bennett and Zeman, 2004). A number of recent studies examining effect measure modification $PM_{2.5}$-related health effects by obesity statues are available and have reported some evidence of increased risk for mortality among obese individuals; however, evidence in studies across the range of effects examined including cardiovascular disease, incident diabetes, reproductive, and development outcomes do not consistently indicate differential risk by obesity status (Supplemental Table S12-3) (U.S. EPA, 2018).

Several studies examined effect measure modification of associations between mortality and long-term $PM_{2.5}$ exposure by obesity status. Overall, there was a trend across studies of increased risk among those who were overweight or obese compared to those of normal weight, though there are some exceptions to this trend across studies, and effect estimates are imprecise (i.e., wide 95% confidence intervals). A number of multicity studies in the U.S., Canada, and Europe reported increased risk for mortality among those who were obese (Villeneuve et al., 2015; Beelen et al., 2014a; Beelen et al., 2014b; Weichenthal et al., 2014; Puett et al., 2009). However, Turner et al. (2011) reported decreasing risk as BMI increased, including a 14% decrease in risk for those overweight compared to normal BMIs and a negative association among obese individuals. Furthermore, it is possible there is some variation by underlying cause of mortality. For example, Pinault et al. (2016) observed marginal decreases in risk for all-cause and cardiovascular mortality among those who were obese, though they reported a 35% increase in risk for respiratory mortality among obese participants. In contrast to these results, a pooled analysis of European cohorts observed that as BMI increased the association between $PM_{2.5}$ and respiratory mortality declined, while the opposite was true for all-cause and cardiovascular mortality (Beelen et al., 2014a; Beelen et al., 2014b; Dimakopoulou et al., 2014).

Studies have also examined a differential risk for a variety of cardiovascular effects by obesity status. In general, studies found little evidence for differences between obese and nonobese individuals, and when changes in association were present, they tended to be modest and imprecise. For example, a registry study of long-term $PM_{2.5}$ exposure and incident hypertension in Ontario, Canada (Chen et al., 2014) reported a decrease in risk for obese participants (HR: 1.07, 95% CI: 0.91, 1.26) compared to nonobese participants (HR: 1.17, 95% CI: 1.04, 1.33). Likewise, an examination of the Nurses' Health Study reported an increased risk in incident cardiovascular disease for obese participants (HR: 1.12, 95% CI: 0.99, 1.30) compared to nonobese participants (HR: 0.99, 95% CI: 0.88, 1.12) (Hart et al., 2015). A number of studies also examined changes in blood pressure with both long-term (Chan et al., 2015; Fuks et al., 2011) and short-term (Hoffmann et al., 2012; Wellenius et al., 2012b) exposures to $PM_{2.5}$ and observed no consistent pattern by obesity status for changes in blood pressure. Other studies examined outcomes such as prevalence of heart disease (Johnson and Parker, 2009) or measures of atherosclerosis (Hoffmann et al., 2009b) and did not observe an increase in risk among those who were obese compared to those with healthy weight.

Several of the studies that examined cardiovascular endpoints related to atherosclerosis and modification by diabetes status, as previously described (Section 12.3.2), also examined potential modification by obesity and observed limited evidence of increased risk among obese participants compared to those or healthy weight. In a study of the MESA cohort, Allen et al. (2009) identified positive $PM_{2.5}$ associations with elevated risk for calcification among obese individuals compared to those of normal weight. Furthermore, in those obese individuals with some or no calcification a positive change in the Agatston score (measure of coronary artery calcification) was observed. A similar study of the MESA cohort estimated the effect of 20 year $PM_{2.5}$ averages on atherosclerosis health measures and found no differences in association by BMI category (Roux et al., 2008). In a German population-based

cohort study (Heinz Nixdorf Recall study) Bauer et al. (2010) found a slightly stronger association between $PM_{2.5}$ exposure and carotid intima-media thickness (CIMT) for obese participants compared to those of normal weight.

Other studies specifically evaluated effect modification by obesity status on associations between markers of inflammation and coagulation, including IL-6, CRP, and fibrinogen. Hoffmann et al. (2009a) and Hertel et al. (2010) conducted analyses from German Heinz Nixdorf Recall Study cohort and found no distinct effect by obesity status on $PM_{2.5}$ associations with fibrinogen or CRP. A Study of Women's Health Across the Nation (SWAN), demonstrated increased CRP for middle aged obese women, though estimates had wide confidence intervals (Ostro et al., 2014).

A limited number of studies investigated effect measure modification by obesity for associations between $PM_{2.5}$ and other health endpoints, such as incident diabetes and reproductive outcomes. Among studies of incident diabetes, results were inconsistent. A study in Ontario, Canada reported decreased risk of developing diabetes among the overweight and obese (Chen et al., 2013), while multicity studies in Denmark (Hansen et al., 2016) and Germany (Weinmayr et al., 2015) reported increased risk among the obese compared to healthy weight. Among studies of reproductive outcomes, insufficient studies were available to report any trends for a specific outcome; however, there was little evidence of modification by obesity status in studies of endometriosis (Mahalingaiah et al., 2014), and gestational diabetes (Robledo et al., 2015). Conversely, in a small study of preeclampsia among predominantly Hispanic women in Los Angeles, Mobasher et al. (2013) reported higher risks among nonobese women based on $PM_{2.5}$ exposures in the first trimester compared to obese women.

Overall, the available evidence is suggestive of increased risk among those who are obese compared to those who are not obese for $PM_{2.5}$-associated health effects. There is a relatively consistent evidence across a small evidence base demonstrating increased risk of $PM_{2.5}$-associated mortality among those who are obese or overweight compared to those of healthy weight. Results from other outcomes were less consistent, although some studies observed increased risk in markers of atherosclerosis as well as incident diabetes. An important limitation across studies was the variability in categorizing obesity, with thresholds defining obesity ranging from a BMI of 27 to 30.6 kg/m^2. Furthermore, many studies did not distinguish between being overweight or obese and included overweight individuals either with obese individuals or with healthy weight individuals.

12.3.4 Elevated Cholesterol

Overview

- Elevated cholesterol is a common chronic condition in the U.S. adult population and is an important risk factor for other serious health conditions associated with $PM_{2.5}$ exposure, such as cardiovascular disease and diabetes.
- The 2009 PM ISA did not evaluate cholesterol status, but some recent studies have examined differences $PM_{2.5}$-associated health effects in the context of lipid disorders. This limited epidemiologic evidence provides evidence of increased risk with short- and long-term $PM_{2.5}$ exposure for those with elevated cholesterol compared to normal cholesterol.
- Additional epidemiologic studies stratifying by cholesterol medication (i.e., statins) usage provide limited evidence of increased risk of cardiovascular disease among statin users compared to those not taking statins.
- **Overall, the evidence is inadequate to determine if adults with elevated cholesterol are at increased risk for $PM_{2.5}$-related health effects.**

Elevated blood cholesterol is a common chronic health condition in the U.S., with the prevalence of hypercholesterolemia in the U.S. adult population approximately 26.0%, as reported by the 1999−2006 National Health and Nutrition Examination Surveys (Fryar et al., 2010). Metabolic disruption, such as dyslipidemia, can increase the risk of other health conditions, such as cardiovascular disease and diabetes. Additionally, as examined in Chapter 6 and Chapter 7, there is some evidence that short-term (Section 6.3.5, Section 7.1.3.3) and long-term (Section 6.3.12, Section 7.2.5.5) $PM_{2.5}$ exposures are associated with changes in blood lipids. While elevated blood cholesterol is an important health risk factor, few studies have explicitly investigated if blood cholesterol status increases the risk of other health outcomes associated with $PM_{2.5}$ exposure.

The PM 2009 ISA (U.S. EPA, 2009) did not evaluate studies examining potential differences in populations based on cholesterol. A limited number of epidemiologic studies have investigated differences between populations with and without high cholesterol, or by statin usage, and observed some evidence of higher risk for $PM_{2.5}$ related mortality and cardiovascular outcomes (Supplemental Table S12-4) (U.S. EPA, 2018). While these studies indicate those with elevated cholesterol, or those who use statins, may have potentially higher risks, overall, there were insufficient studies available to determine if cholesterol status consistently modifies health outcomes associated with $PM_{2.5}$ exposure.

In a study of 13 northeastern U.S. states, using data from the NHS cohort, Puett et al. (2009) evaluated the potential for effect measure modification by hypercholesterolemia status with $PM_{2.5}$ exposure over the 12-months prior to all-cause mortality, or a fatal coronary heart disease (CHD) event. In stratified analyses, the authors observed increased risk among those with hypercholesterolemia (HR: 1.53, 95% CI: 1.15−2.03) compared to those without hypercholesterolemia (HR: 1.04, 95% CI: 0.77−1.40). Puett et al. (2009) observed a similar trend among a smaller subset of fatal CHD cases. A

small study of myocardial infarction hospital admissions in Rochester, NY also observed a larger positive association among patients with history of dyslipidemia (Gardner et al., 2014).

In addition to studies with information on direct measures of blood cholesterol or patient history of dyslipidemia, several studies stratified study populations by use of statins or lipid-lowering medication. Long-term exposure studies in the U.S. and Germany (Bauer et al., 2010; Allen et al., 2009), as well as a meta-analysis of randomized controlled trials in Los Angeles (Künzli et al., 2010) observed increased risk of atherosclerosis associated with $PM_{2.5}$ exposure among those using statins compared to those not using statins. Studies of other health measures and long-term $PM_{2.5}$ exposure, such as history of peripheral vascular disease (Hoffmann et al., 2009b), and platelet counts (Viehmann et al., 2015) also observed increased risk among individuals using statins. A U.S. based study, using data from the MESA cohort, did not observe any substantial changes in $PM_{2.5}$-related flow-mediated dilation; however, they observed a positive association in baseline arterial diameter among those using statins compared to no change for those not using statins (Krishnan et al., 2012). Conversely, studies of short- and long-term exposure that investigated systemic inflammation found decreased responses for biomarkers of systemic inflammation among those using statins (Viehmann et al., 2015; Ostro et al., 2014; Hertel et al., 2010); however, many statins have anti-inflammatory properties complicating interpretation of these results.

Overall, the limited evidence is inadequate to determine if elevated cholesterol increases risk for $PM_{2.5}$-related health effects compared to cholesterol in the normal range. A single long-term exposure study reported elevated risk among those with hypercholesterolemia for $PM_{2.5}$-related mortality, while a single short-term study reported elevated risk of ST-Elevation Myocardial Infarction. Several studies examining biomarkers or preclinical measures of atherosclerosis and vascular function provide some evidence of elevated cardiovascular disease risk among statin users; however, the evidence base is small. Other studies examined if statin usage modified $PM_{2.5}$-related systemic inflammation; however, many statins have known anti-inflammatory properties, making these studies less informative in determining whether those with elevated cholesterol exhibited differential subclinical responses due to $PM_{2.5}$ exposure. Further limitations among studies of statins include the relatively low proportion of participants who used statins, leading to less precise estimates (i.e., wide 95% confidence intervals), as well as the difficulty in interpreting how representative statin prescription information is for control of blood lipid disorders among populations using statins.

12.3.5 Pre-existing Respiratory Disease

Overview

- The most common chronic respiratory diseases in the U.S. are asthma and COPD. Asthma affects a substantial fraction of the U.S. population, and it is the leading chronic disease among children. COPD primarily affects older adults and contributes to compromised respiratory function and underlying pulmonary inflammation.
- There is strong evidence indicating $PM_{2.5}$-associated respiratory effects among those with asthma, which forms the primary evidence base for the likely to be causal relationship between short-term exposures to $PM_{2.5}$ and respiratory health effects (Chapter 5).
- Few studies are available from the recent literature or in the 2009 PM ISA that inform whether those with asthma are at disproportionate risk for $PM_{2.5}$-related health effects compared to those without asthma.
- While there is some evidence of $PM_{2.5}$-related health effects in individuals with COPD, there are few studies from the current and previous ISAs with stratified analyses to compare effects in individuals with and without COPD
- **Overall, there is suggestive evidence that individuals with respiratory disease, particularly asthma, may be at increased risk for $PM_{2.5}$-related health effects compared to those without respiratory disease.**

Asthma

Approximately 8.3% of adults and 8.4% of children (age <18 years) in the U.S. currently have asthma (Blackwell and Villarroel, 2018), and it is the leading chronic illness affecting children. With regard to consideration of those with asthma potentially being at increased risk for a $PM_{2.5}$-related health effect, it is important to note that individuals with asthma, and children, tend to have a higher degree of oronasal breathing, which can result in greater penetration of PM into the lower respiratory tract (Section 4.1.3). Furthermore, there is limited evidence demonstrating that individuals with asthma may have altered clearance of particles (Section 4.3.4).

The 2009 PM ISA concluded that individuals with asthma may be more susceptible to health effects related to PM based on a limited number of epidemiologic studies for respiratory effects and controlled human exposure and animal toxicological studies demonstrating biological plausibility for asthma exacerbation with exposures to $PM_{2.5}$. Consistent with this, recent evidence evaluated in this ISA supports that there is likely to be a causal relationship between short-term exposure to $PM_{2.5}$ and respiratory effects, based primarily on evidence for asthma exacerbation in epidemiologic studies (Section 5.1.2) with supporting evidence across disciplines that provides biological plausibility (Section 5.1.1). Given this evidence, it is clear that individuals with asthma experience $PM_{2.5}$-related respiratory effects; however, evidence informing an increase in risk compared to those without asthma is limited.

There continue to be few studies that provide comparisons between individuals with and without asthma (Supplemental Table S12-5) (U.S. EPA, 2018). The 2009 PM ISA (U.S. EPA, 2009) included only a handful of epidemiologic and controlled human exposure studies examining $PM_{2.5}$ or CAPs exposures that provided some evidence for increased risk. Recent evidence is also limited to a few epidemiologic studies with stratified analyses for asthma for a variety of disparate outcomes. Of these studies, Watanabe et al. (2015) and Prieto-Parra et al. (2017) are most informative as they examined respiratory outcomes (i.e., lung function and symptoms) in children with and without asthma. Both studies demonstrated positive associations with short-term exposures to $PM_{2.5}$ for those without asthma, but symptoms and lung function decrements were of greater magnitude in children with asthma.

Other studies examined nonrespiratory outcomes. A study measuring cytokine responsiveness in blood samples collected from children with and without asthma in Germany demonstrated $PM_{2.5}$-related proinflammatory responses in children with asthma that were not observed in children without asthma for short-term exposures. In a multicity U.S. study in adults, $PM_{2.5}$ associated lung cancer mortality was greater in those with asthma compared to those without provide some evidence for increased risk in those with asthma compared to those without (Klümper et al., 2015; Turner et al., 2011). Bunch et al. (2011) conducted a study in Utah of hospital admissions with a primary diagnosis of atrial fibrillation and observed generally positive associations with $PM_{2.5}$ in those with and without asthma. In a study of diabetes incidence in Ontario, Canada, Chen et al. (2013) observed individuals with asthma to be at slightly decreased risk for diabetes with long-term exposures to $PM_{2.5}$ compared to those without.

Chronic Obstructive Pulmonary Disease (COPD)

Chronic lower respiratory disease, including COPD, was ranked as the third leading cause of death in the U.S. in 2011 (Hoyert and Xu, 2012). COPD comprises chronic bronchitis and emphysema and affects approximately 6.8 million adults in the U.S., respectively (Table 12-2). Given that people with COPD have compromised respiratory function and underlying systemic inflammation, it is plausible that they could be at increased risk for an array of $PM_{2.5}$-related health effects. Furthermore, there was some evidence to suggest differences in dosimetry, including greater deposition and impaired mucociliary clearance, that is also described in this ISA (Sections 4.2.4.7 and 4.3.4).

The 2009 PM ISA (U.S. EPA, 2009) described inconsistent results across a small evidence base examining differential $PM_{2.5}$-related respiratory effects in individuals with COPD and those without. In the current review, there continues to be limited evidence examining differential risk by COPD status and most of the available studies have focused on cardiovascular outcomes (Supplemental Table S12-5) (U.S. EPA, 2018). Wang et al. (2017) and Turner et al. (2011) observed greater risk for mortality associated with long-term exposures to $PM_{2.5}$ for those with COPD in a multicity study in the U.S. However, studies for cardiovascular hospitalizations (i.e., atrial fibrillation, myocardial infarction, acute coronary syndrome, and heart failure), incident hypertension, and diabetes incidence did not consistently demonstrate that those with COPD are at greater risk than those without in studies of short- and long-term

$PM_{2.5}$ exposures (Chen et al., 2014; Chen et al., 2013; Bunch et al., 2011; Belleudi et al., 2010; Rich et al., 2010; Haley et al., 2009). There are no recently published controlled human exposure studies that have examined health effects in individuals with COPD.

Despite limited evidence from epidemiologic and experimental studies examining $PM_{2.5}$-related health effects in those with and without pre-existing COPD, the evidence characterized in Chapter 5 demonstrates that there is evidence of COPD exacerbation associated with short-term exposure to $PM_{2.5}$ (Section 5.1.4), contributing to the conclusion of a "likely to be causal" relationship. In particular, epidemiologic studies report positive associations between $PM_{2.5}$ and hospital admissions and emergency department visits for COPD, with supporting evidence from panel studies demonstrating COPD exacerbation. Epidemiologic evidence is supported by limited experimental evidence of COPD-related effects, which provides biological plausibility for COPD in response to $PM_{2.5}$ exposure. This evidence indicates that $PM_{2.5}$-associated effects are observed in those with COPD, but it does not indicate if this risk is disproportionate compared to those without COPD.

Taken together, the collective evidence is suggestive that those with pre-existing respiratory diseases, particularly asthma and COPD, are at increased risk for $PM_{2.5}$-related health effects compared to those without pre-existing respiratory diseases. For asthma, there is strong evidence across disciplines indicating that there is likely to be a causal relationship for respiratory effects and $PM_{2.5}$ exposures based on asthma exacerbation, but few studies have conducted stratified analyses to inform increased risk. For COPD, the evidence base is limited to a few studies with inconsistent results for no respiratory outcomes.

12.4 Genetic Factors

Overview

- Variability in genetic background is known to contribute to the wide range of biological responses and diseases that are observed in the human population.
- Although limited, recent epidemiologic evidence is consistent with that characterized in the 2009 PM ISA, demonstrating differential risk for $PM_{2.5}$-related responses in individuals with variants in genes in the glutathione pathway that has a key role in oxidative stress.
- This is coherent with evidence supporting the biological plausibility for $PM_{2.5}$-related health effects as oxidative stress is an important early response following exposure.
- Several other genetic variants and epigenetic factors have been examined, but evidence is limited for each.
- **Overall, the evidence is suggestive that individuals with variants in the glutathione pathway are at increased risk for $PM_{2.5}$-related health effects compared to those without a variant genotype.**

Genetic variation in the human population is known to contribute to numerous diseases and differential physiologic responses. The potential for genetic background to modify responses to exposure to PM was evaluated in the 2009 PM ISA (U.S. EPA, 2009) and the biological plausibility of individuals with certain genotypes known to result in reduced function in genes encoding antioxidant enzymes being at increased risk for respiratory effects related to ambient air pollution was described. Though the evidence base for any particular genetic polymorphism was limited, the 2009 ISA concluded that evidence suggested that specific genetic polymorphisms could potentially increase the susceptibility of an individual to health effects related to PM exposure. In the recently published literature, several additional studies are available that examine genes related to antioxidant defense, inflammation, and lipid metabolism (Supplemental Table S12-6) (U.S. EPA, 2018).

Glutathione is the primary antioxidant defense in the body and is critical to protecting against oxidative stress. Because of this, variant genotypes in the glutathione pathway have been the most commonly studied with regard to health effects related to PM because oxidative stress is known to be one of the early biological responses following exposure (Sections 5.1.2, 5.2.1, 6.1.1, and 6.2.1). The 2009 PM ISA described results from a few studies that observed those with GSTM1 null genotypes to be at increased risk for cardiovascular effects related to $PM_{2.5}$ exposures (Schneider et al., 2008; Chahine et al., 2007; Schwartz et al., 2005). Of the recent epidemiologic evidence examining genetic variants in the oxidative stress pathway, only one study provides additional evidence for cardiovascular outcomes. Hampel et al. (2010) demonstrated that in adults with prior MI, $PM_{2.5}$-related QTc prolongation was greater in individuals with the minor allele for NFE2L2 rs1364725 compared to those with the major allele. Other recent evidence examines respiratory outcomes in children and provides additional support for effect measure modification by genetic background. For example, in a study of elementary and middle school children in Taiwan, $PM_{2.5}$-related increases in leukocytes and neutrophils in nasal lavage samples were greater in those with GSTM1 null genotypes compared to GSTM1 positive (Chen et al., 2016). Another study examined haplotypes in the glutathione synthetase gene (GSS) utilizing data from the Children's Health Study in southern California. While stratification for GSS haplotype 010000 demonstrated larger decrements in FVC in association with long-term $PM_{2.5}$ concentrations compared to other haplotypes, slightly smaller decrements in FEV1 and MMEF were observed for haplotype 010000 (Breton et al., 2011). Fuertes et al. (2013) conducted a pooled-analysis of 6 birth cohorts across Europe to examine associations in doctor-diagnosed allergic rhinitis at 7−8 years of age among variants for SNPs in GSTP1, TNF, TLR2, and TLR4. This study found positive associations for $PM_{2.5}$ and allergic rhinitis across all children, and magnitude of association in children with the minor alleles for GSTP1 (rs1138272) was slightly larger than those homozygous for the major allele. In addition, the magnitude of association between $PM_{2.5}$ and allergic rhinitis was slightly larger for those having minor alleles for SNPs in TNF (rs1800629) and TLR4 (rs10759930), implicating an inflammatory response with long-term exposure to $PM_{2.5}$.

Other studies examined a diverse range of genetic variants and outcomes. Wilker et al. (2011) examined modification of the $PM_{2.5}$-associated changes in adhesion molecules by genetic variants in

micro-RNA processing genes in the participants from the Normative Aging Study. Relatively little is known about the role of these genes relative to inflammation, but this study demonstrated that those having the minor allele for GEMIN4 (rs1062923) had lower levels of ICAM-1 and VCAM-1 in association with short-term $PM_{2.5}$ exposures. Ren et al. (2010) also used data from the NAS to evaluate genetic background, though the focus of this study $PM_{2.5}$-related HRV and modification by polymorphisms in lipid metabolism and endothelial function. A number of polymorphisms were examined in APOE, LPL, and VEGF and results demonstrated that the minor allele for the SNPs examined was associated with smaller reductions in HRV. Lastly, Hampel et al. (2012) examined effect modification by SNPs associated with cardiovascular outcomes as identified in the literature and demonstrated inconsistent results for CHT1 rs333229, rs2966762, rs1871841 and $PM_{2.5}$-related decrements in HRV, though the relevance of these SNPs is not clear.

Some recently published animal studies have also examined genetic variants, particularly in relation to PM-induced metabolic effects. Experimental genetic knockout studies in mice exposed to $PM_{2.5}$ support a role for TLR4 activation of Nox2 leading to a systemic inflammation (Kampfrath et al., 2011). In another study of mice deficient in the CC-chemokine receptor 2 (CCR2) gene, defective monocyte recruitment during immune responses were protected from $PM_{2.5}$ and high fat diet induction of hepatic steatosis, insulin resistance, systemic and peripheral inflammation (Liu et al., 2014). Other studies utilized a mouse model deficient in the neutrophil NADPH oxidase gene (required for superoxide anion production) and found that they were protected from CAPs-induced increases in superoxide production, insulin resistance, increase in abdominal mass and visceral adiposity, and fibrosis in mice (Zheng et al., 2015; Xu et al., 2010).

Recent evidence has also included the examination of DNA methylation and the underlying role it may play in $PM_{2.5}$-related health effects. Across the studies of DNA methylation (Peng et al., 2016; Lepeule et al., 2014; Bind et al., 2012; Salam et al., 2012), hypermethylation of a number of genes have been examined including iNOS, ICAM1, CRAT, ICAM, IFN-gamma, IL-6, iNOS, OGG1, GCR, F3, and TLR2. While there is some evidence that hypermethylation of these genes may play a role in mediating $PM_{2.5}$-related health effects when compared to hypomethylation, evidence is too limited to draw conclusions.

Overall, the evidence is suggestive that individuals with genetic variants in the glutathione pathway are at increased risk for $PM_{2.5}$-related health effects compared to those without variant genotypes. There is consistent evidence from a handful of studies in the recent literature and the 2009 PM ISA demonstrating that variants in the glutathione pathway may increase the risk of a PM-related health effect that is supported by evidence for biological plausibility and a role for oxidative stress in initial responses to exposures to $PM_{2.5}$. A variety of other variants have been examined in addition to studies of DNA methylation in $PM_{2.5}$-related health effects, but the evidence is too limited to determine if they modify risk.

12.5 Sociodemographic Factors

12.5.1 Lifestage

The 2009 ISA for Particulate Matter (U.S. EPA, 2009) discussed some evidence for increased risk of health effects related to PM exposure among different lifestages (i.e., children and older adults). Lifestage refers to a distinguishable time frame in an individual's life characterized by unique and relatively stable behavioral and/or physiological characteristics that are associated with development and growth (U.S. EPA, 2014). Differential health effects of PM across lifestages could be due to several factors. With regard to children, the human respiratory system is not fully developed until 18−20 years of age, and therefore, it is biologically plausible that children may have intrinsic risk for respiratory effects due to potential perturbations in normal lung development. Older adults, typically considered those 65 years of age or greater, have weakened immune function, impaired healing, decrements in pulmonary and cardiovascular function, and greater prevalence of chronic disease (Table 12-2), which may contribute to, or worsen health effects, related to PM exposure. Also, exposure or internal dose of PM may differ across lifestages due to varying ventilation rates, increased oronasal breathing at rest, and time-activity patterns. The following sections present the evidence comparing lifestages from the recent literature, which builds on the evidence presented in the 2009 Particulate Matter ISA (U.S. EPA, 2009).

12.5.1.1 Children

Overview

- Children makeup a substantial fraction of the population and often have unique risks because of their continuous growth and development.
- Limited recent evidence indicates that children may have higher $PM_{2.5}$ exposures than adults and that there are dosimetric differences in children compared to adults.
- Strong evidence demonstrates $PM_{2.5}$-associated health effects in children, particularly from recent epidemiologic studies of short-term $PM_{2.5}$ exposure and impaired lung function growth, decrements in lung function, and asthma development.
- Evidence from stratified analyses in the current and previous ISAs demonstrates generally positive associations with $PM_{2.5}$ exposure of similar magnitudes for children and adults.
- **Overall, evidence is adequate that children are at increased risk for $PM_{2.5}$-related health effects, with the strongest evidence from associations with effects specifically examined in children (e.g., lung function growth and asthma development).**

Children may be particularly at risk for health effects related to ambient $PM_{2.5}$ exposures compared to adults due to (1) children's developing respiratory system, (2) children's increased ventilation rates relative to body mass compared to adults, and (3) the increased proportion of oral

breathing observed among children, particularly boys, relative to adults. Such oral breathing can result in higher exposures compared to nasal breathing (Section 4.2.4.2). In addition, children tend to spend more time outdoors, and, consequently, have the potential for greater exposure to ambient $PM_{2.5}$. Consistent with these opportunities for greater exposure, Bell and Ebisu (2012) observed higher $PM_{2.5}$ exposures among children and young adults (0−19 years) compared to adults (20−64 years). According to the 2010 census, 24% of the U.S. population is less than 18 years of age, with 6.5% less than age 6 (Howden and Meyer, 2011). The large proportion of children within the U.S. supports the public health significance of characterizing the risk of PM-related health effects among children.

While there is some evidence to inform dosimetric and exposure differences among children (Sections 4.2.4 and 4.3.4), there has been little evidence from stratified analyses to demonstrate children being at increased risk of the health effects associated with $PM_{2.5}$ exposure compared to adults. That is, positive effect estimates are often observed in stratified analyses of children, but these effect estimates are similar in magnitude to those observed for adults (Supplemental Table S12-7) (U.S. EPA, 2018). For example, recent studies of short-term $PM_{2.5}$ exposure and respiratory hospital admissions or ED visits report consistent, positive associations among analyses restricted to children; the magnitude of these associations is similar to those observed for adults (Atkinson et al., 2016; Samoli et al., 2016; Xu et al., 2016). Overall, the evidence from recent studies is consistent with previously evaluated evidence. The 2004 PM AQCD, summarizing studies examining either PM_{10} or $PM_{2.5}$, concluded that the "rather small group of studies does not show striking differences in effect estimates from analyses across age group strata" (U.S. EPA, 2004). The 2009 PM ISA(U.S. EPA, 2009) presented evidence from a single study of $PM_{2.5}$ (Mar et al., 2004) that observed stronger respiratory effects in children (7−12 years) compared to adults (20−51 years).

Other epidemiologic studies did not stratify results by lifestage, but instead restricted the analyses to children, and provide evidence for the occurrence of effects for a particular lifestage (i.e., effects that can only be observed in children). This is the case for a number of longitudinal studies of long-term $PM_{2.5}$ exposure and lung development (Section 5.2.2.1.1), lung function (Section 5.2.2.2.1), and asthma development (Section 5.2.3.1) in children. Recent longitudinal studies, particularly those from the Children's Health Study (CHS), are consistent with and extend the evidence that was available in the 2009 PM ISA demonstrating that long-term $PM_{2.5}$ exposure is associated with impaired lung function growth, decrements in lung function, and increased incidence of asthma development in children. Toxicological studies provide support for these associations in children as pre- and post-natal exposure to ambient levels of urban particles were found to impair mouse lung development. Recent results from the CHS not only corroborate previous results, but they also indicate improvements in lung development in association with declining $PM_{2.5}$ concentrations (Gauderman et al., 2015). In addition, a number of recent prospective and retrospective cohort studies based in North America and Europe provide evidence that long-term $PM_{2.5}$ exposure is associated with asthma development in children (Section 5.2.3.1).

Additional studies compared different age groups within the childhood lifestage. (Ding et al., 2016) evaluated asthma ED visits in Chongqing, China and observed higher effect estimates among 2−5 year old children compared to 0−1 or 6−18 year old children, though the inability to reliably diagnose asthma in younger children may contribute to the heterogeneity in these results. When considering ED visits due to pneumonia in Jinan, China, (Lv et al., 2016) reported higher effect estimates for infants (<1 year old) and young children (1−4 years old) compared to older children (5−15 years old).

In summary, the evidence demonstrating $PM_{2.5}$-associated health effects in children is adequate to conclude that children are at increased risk for $PM_{2.5}$-related health effects. There is strong evidence that children are at increased risk to the effects of $PM_{2.5}$ exposure, based primarily on studies examining effects specific to children. Epidemiologic studies of long-term $PM_{2.5}$ exposure demonstrate associations with impaired lung function growth (Section 5.2.2.1.1), decrements in lung function (Section 5.2.2.2.1), and increased incidence of asthma development in children (Section 5.2.3.1). The evidence from stratified analyses provides limited evidence that children are at increased risk of $PM_{2.5}$-related health effects compared to adults. In addition, there is some evidence indicating that children receive higher $PM_{2.5}$ exposures than adults and there are dosimetric differences in children compared to adults that can contribute to higher doses. Finally, there is emerging evidence from two Chinese studies suggesting that ages 1 to 5 years could be a critical window among children during which they experience respiratory health effects associated with short-term $PM_{2.5}$ exposure.

12.5.1.2 Older Adults

Overview

- Older adults represent an increasing portion of the U.S. population and often have pre-existing diseases/conditions that may compromise biological function.
- Limited recent evidence does not indicate that older adults have higher $PM_{2.5}$ exposures than younger adults, though older adults could receive higher doses due to dosimetric differences.
- Consistent evidence demonstrates $PM_{2.5}$-associated health effects in older adults, particularly between short- and long-term $PM_{2.5}$ exposure and mortality as well as cardiovascular or respiratory morbidity.
- Evidence from stratified analyses in the current and previous ISAs demonstrates similar associations with $PM_{2.5}$ exposure in older adults and younger adults.
- Animal toxicological and controlled human exposure studies provide additional evidence for the occurrence of effects among this particular lifestage, but do not inform whether or not this lifestage is at increased risk to the health effects of $PM_{2.5}$.
- **Overall, while $PM_{2.5}$-associated effects are observed in older adults, evidence is inadequate to determine if older adults are at increased risk for effects compared to younger adults.**

Older adults are a potentially at increased risk population due to the higher prevalence of pre-existing cardiovascular and respiratory diseases found in this age range compared to younger life stages. The increased risk in this lifestage can likely be attributed to the gradual decline in physiological processes that occurs with aging (U.S. EPA, 2006). Therefore, some overlap exists between populations considered to be at-risk due to pre-existing disease and lifestage (i.e., older adults) (Kan et al., 2008). According to the 2014 National Population Projections issued by the U.S. Census Bureau, approximately 14.9% of the U.S. population is age 65 years or older, and by 2040, this fraction is estimated to grow to 21.7% (U.S. Census Bureau, 2014); accessed November 9, 2017. Thus, this lifestage represents a substantial proportion of the U.S. population demonstrating the public health importance of characterizing the potential for increased risk for health effects related to $PM_{2.5}$ exposure in this age group.

The 2009 ISA for Particulate Matter (U.S. EPA, 2009) indicated that compared with younger adults, older adults (typically ages 65 years and older) may be susceptible to PM-related cardiovascular effects. The evidence from epidemiologic, controlled human exposure and animal toxicological studies were generally consistent and coherent in supporting this conclusion, though some geographic heterogeneity in the pattern of associations among studies conducted in U.S. and non-U.S. locations was acknowledged. Additional evidence for associations between short-term PM exposure and respiratory morbidity and mortality was also available, and generally limited to results from epidemiologic studies.

Recent studies contribute to the existing body of evidence evaluating whether: (1) older adults experience higher exposures to $PM_{2.5}$ compared to younger adults; (2) stratified analyses conducted in epidemiologic studies support increased risk of health effects among older adults compared to younger adults; (3) animal toxicological, controlled human exposure, and epidemiologic analyses restricted to older populations provide coherence for the occurrence of effects for this particular lifestage, and (4) there is evidence for variability in associations among different age groups within the older adults lifestage.

Clearance of $PM_{2.5}$ from all regions of the respiratory tract decreases with increasing age beyond young adulthood in both humans and laboratory animals, indicating that older adults could receive higher doses of $PM_{2.5}$ compared to younger adults (Section 4.3.4). However, there is little evidence indicating that older adults are systemically exposed to higher concentrations of $PM_{2.5}$ than other lifestages. Miranda et al. (2011) observed that older adults (i.e., 65+ years) were less likely to live in counties with the highest daily or annual $PM_{2.5}$ concentrations. Consistent with this, Bell and Ebisu (2012) observed similar $PM_{2.5}$ exposures among older adults (65+ years) compared to adults (20−64 years).

A relatively large number of recent epidemiologic studies of short- and long-term $PM_{2.5}$ exposure and cardiovascular and respiratory health effects, as well as mortality, report generally consistent, positive associations among analyses restricted to older adults, though the magnitude of these associations is similar to those observed for younger adults (Supplemental Figure S12-8) (U.S. EPA, 2018). Studies of short-term $PM_{2.5}$ exposure and cardiovascular or respiratory effects generally consist of evaluations of hospital admission, emergency department visits, or mortality conducted in the U.S., Canada, Europe, or China. Generally, positive associations were observed for both younger adults and older adults with no

indication that the associations observed for older adults were consistently greater in magnitude. A number of studies of long-term $PM_{2.5}$ exposure evaluated associations with cardiovascular effects among older adults and younger adults and did not observe stronger magnitude of effects among the older adults. Evaluations of subclinical cardiovascular effects (e.g., blood pressure, measures of vascular functions, concentrations of circulating biomarkers) were somewhat less consistent in demonstrating positive associations with long-term $PM_{2.5}$ concentrations compared to cardiovascular mortality. Similar to the results of studies of long-term $PM_{2.5}$ exposure and cardiovascular mortality, both short- and long-term $PM_{2.5}$ exposures were consistently associated with total (nonaccidental) mortality, but there was no indication that these associations were of greater magnitude in older adults compared to younger adults (Supplemental Figure S12-8) (U.S. EPA, 2018).

Though there are a relatively large number of epidemiologic studies evaluating the associations between $PM_{2.5}$ concentrations and health effects as detailed in (Supplemental Figure S12-8), it is noteworthy that there is substantial variability in the age ranges included as the reference group. For example, sometimes the reference group included all individuals less than a certain age (e.g., 60, 65, or 70 years), while other times the reference group included individuals from a smaller, more restricted range of ages (e.g., 35−64, 40−69, or 45−64 years). Such variability in the reference groups makes it difficult to make comparisons about the magnitude of effects across studies, though it should not affect inferences about whether older adults are at increased risk of $PM_{2.5}$-related health effects compared to younger adults. Additionally, it is possible that the results of stratified analyses could be affected by publication bias; several studies conducted stratified analyses by lifestage but did not report quantitative results when no differences were observed across strata. While likely to exist, such publication bias is unlikely to influence any inferences drawn from the body of evidence evaluated here, as these studies also did not generally observe differences in associations across age strata. Finally, some studies compared associations for older adults to those for all ages (including the older adults). Since these are not truly stratified analyses, and there is overlap between the two groups, results from those studies are not considered here nor included in Supplemental Figure S12-8 (U.S. EPA, 2018)

Several animal toxicological, controlled human exposure, and epidemiologic studies did not stratify results by lifestage, but instead restricted the analyses to older individuals, and can provide coherence and biological plausibility for the occurrence of effects among this particular lifestage. When considering animal toxicological studies, the 2009 PM ISA reported that exposure to $PM_{2.5}$ CAPs was associated with arrhythmias in older, but not younger rats. Recent studies extend the evidence that was available in the 2009 PM ISA from controlled human exposure studies demonstrating that $PM_{2.5}$ CAPs exposure is associated with decreases in HRV in older, healthy adults. In Copenhagen, Denmark, Hemmingsen et al. (2015) exposed older overweight, but healthy men and women to traffic-related air pollution (TRAP) that was nonfiltered or particle filtered and observed decreased high frequency measurements and increased low frequency measurements when nonfiltered TRAP was compared to particle filtered. In a dietary intervention study, Tong et al. (2012) reported that after a 28-day

supplementation period with olive oil, there was a lower HF/LF ratio immediately after CAP exposure in older adults. There were no changes in HRV time domain measurements found in this study.

Recent epidemiologic panel studies have observed associations with cardiovascular morbidity and $PM_{2.5}$ exposure among older adults (Sections 6.2.2.2, 6.2.6.2, and 6.2.11.1). In one study of older adults with ischemic heart disease in nursing homes in Los Angeles, CA, $PM_{2.5}$ concentrations were associated with ST-segment depression (Delfino et al., 2011). In addition, panel studies of older adult populations report generally consistent evidence for an association between short-term $PM_{2.5}$ exposure and BP, particularly studies including participants living in nursing homes or senior communities which allow for improved exposure assessment (Jacobs et al., 2012; Wellenius et al., 2012b; Liu et al., 2009). Among studies of inflammatory markers, the evidence was less consistent. Some panel studies of older adults observed positive associations between $PM_{2.5}$ and inflammatory IL6 and TNF in a (Wittkopp et al., 2013; Delfino et al., 2009), while others did not (Wang et al., 2016a; Rich et al., 2012; Liu et al., 2009).

Additional studies compared different age groups within the older adult lifestage. For example, Bell et al. (2015) observed higher magnitude effect estimates among those 85+ years compared to those aged 65−74 or 75−84 years for cardiovascular mortality, but not for respiratory mortality and short-term $PM_{2.5}$ exposure. Conversely, Madsen et al. (2012) observed higher effects among those aged 65−74 compared to those aged 74−85 or 85+ when examining short-term $PM_{2.5}$ exposure and total mortality. When evaluating long-term $PM_{2.5}$ exposure and total mortality and cardiovascular mortality, Crouse et al. (2015) observed positive associations for both men and women across age groups (i.e., 60−69, 70−79, 80−89 years). This is inconsistent with evidence reported in the 2009 PM ISA, where limited evidence indicated declines in effect estimates for mortality with increasing age, starting at 60 until there was generally a null association among individuals 85+ years. Overall, there is no consistent evidence that risk varies for different age groups within the older adult lifestage.

Overall, there continues to be evidence supporting that $PM_{2.5}$-associated health effects are present in older adults; however, the evidence is inadequate to determine whether older adults are at increased risk of $PM_{2.5}$-related health effects when compared to younger adults. Among epidemiologic studies of short- and long-term $PM_{2.5}$ exposure, there is little evidence to support increased risk of health effects among older adults compared to younger adults. While there is limited evidence that changes in physiology could result in decreased ability to clear $PM_{2.5}$ from the respiratory tract, there is no evidence that older adults are exposed to high $PM_{2.5}$ concentrations than younger adults. Animal toxicological, controlled human exposure, and epidemiologic studies continue to support that older adults are at risk to the effects of $PM_{2.5}$ exposure, especially cardiovascular effects. This evidence comes mainly from epidemiologic panel studies of short-term $PM_{2.5}$ exposure observing associations with cardiovascular morbidity among older adults residing in nursing homes, decreases in HRV in controlled human exposure studies of older adults, and increased arrhythmias in older rats in animal toxicological studies. Studies that did not stratify results by lifestage, but instead restricted the analyses to older individuals, provide coherence and biological plausibility for the occurrence of effects among this

particular lifestage. Finally, there is no consistent evidence to indicate that any age groups within the older adult lifestage have higher risks than others.

12.5.2 Sex

Overview

- Males and females in the U.S. have differing health concerns; for example, health effects related to reproduction (e.g., sperm motility in males and pregnancy outcomes in females) are sex-specific.
- For health outcomes concerning both sexes, there is some evidence of higher mortality in males than in females from long-term exposures to $PM_{2.5}$.
- For other health outcomes from long-term $PM_{2.5}$ exposure, and for outcomes from short-term $PM_{2.5}$ exposure, there is no clear pattern of increased risk for either sex.
- **Overall, the evidence in inadequate to determine if males are at increased risk for $PM_{2.5}$-related health effects compared to females.**

A large number of health conditions resulting in morbidity and mortality have been shown to differ by sex. The Centers for Disease Control and Prevention estimate that a male born in the U.S. in 2012 has a life expectancy of 76.4 years, while a female has a life expectancy of 81.2 years (Arias et al., 2016). Due to both biological and social differences it is reasonable to consider that the risks of exposure to air pollution may differ between sexes. For example, exposure risks related to gestation and fetal development will primarily concern females and differences between sexes in time spent at the workplace or at home (U.S. BLS, 2017) will potentially contribute to differences in PM exposure. Sex-specific biological risks related to fertility are described in Chapter 9 of this document. Briefly, health outcomes specifically concerning males include potentially decreased sperm motility (Radwan et al., 2015; Hammoud et al., 2009). Outcomes specifically concerning females involve pregnancy-related morbidity; this includes outcomes such as gestational hypertension, preterm birth, and low birth weight. Overall, evidence in Chapter 9 was considered suggestive of a causal relationship between $PM_{2.5}$ exposure and these sex-specific reproductive health concerns.

The 2009 PM ISA (U.S. EPA, 2009) concluded that neither sex had a consistently stronger association between PM exposure and health effects. Evidence from the recent literature generally supports this conclusion, though there may be specific outcomes that differ in risk by sex. Due to the lower life expectancy of males in the U.S., females have been selected as the "reference" category; however, either sex could be considered a potential "at-increased-risk" group of interest.

There is some evidence for differences in mortality due to PM exposure by sex, with males having potentially stronger associations than females (Supplemental Table S12-9) (U.S. EPA, 2018). Di et al. (2017) analyzed long-term $PM_{2.5}$ exposure and mortality in the U.S. Medicare population and found

a higher association for males (RR: 1.087, 95% CI: 1.083, 1.090) than for females (RR: 1.060, 95% CI: 1.057, 1.063). However, this was not the case for Medicaid-eligible (low-income) Medicare recipients, who did not display this difference between the sexes. While this is among the more comprehensive studies on this topic, other results of national U.S.-based long-term exposure studies have been inconsistent. A study by Wang et al. (2017) which includes an overlapping study population with that of Di et al. (2017) focuses on Medicare beneficiaries in the Southeastern U.S. only, and consistent with Di et al. (2017), the mortality-PM association within this region was also stronger for males than for females. Other studies report results ranging from males having roughly the same risk (Thurston et al., 2015) to slightly lower risk (Zeger et al., 2008) than females. In Canada, Crouse et al. (2015) reported higher PM-associated mortality among males in each age bracket considered and higher mortality among males as a group overall. The short-term $PM_{2.5}$-related effect differences on mortality by sex are negligible, with Huang et al. (2012) and Madsen et al. (2012) reporting slight increases for all-cause mortality in males and Samoli et al. (2013) reporting a slight decrease for males for non-accidental mortality.

Other studies have examined effect measure modification by sex for $PM_{2.5}$-associated cardiovascular effects. In a study of hospitalizations for U.S. Medicare beneficiaries, Bell et al. (2015) reported higher risks for females than for males from short-term $PM_{2.5}$ exposure for cardiovascular outcomes overall, as well as for heart rhythm disturbance and heart failure specifically. However, this observation was found to vary geographically, and this disparity was more pronounced in the Northeast than in other regions of the U.S. (Bell et al., 2015). In contrast, a study of short-term $PM_{2.5}$ exposure in Little Rock, Arkansas demonstrated that males had a greater association than females for cardiovascular-related emergency room visits (Rodopoulou et al., 2015). Short-term exposure studies conducted outside the U.S. have reported associations larger in magnitude for cardiovascular mortality in females (Milojevic et al., 2014) and congenital heart disease in males (Ye et al., 2016). However, in general for short-term exposure to $PM_{2.5}$, there is little evidence supporting the presence of disparities in cardiovascular outcomes between males and females. Specifically, in studies examining cardiovascular outcomes overall (Lanzinger et al., 2016; Kloog et al., 2014), cardiovascular mortality (Su et al., 2015), cardiac arrest (Silverman et al., 2010), heart failure (Haley et al., 2009), hypertension (Brook and Kousha, 2015), infarctions (Weichenthal et al., 2016; Rich et al., 2010), pulmonary embolism (Dales et al., 2010), and venous thrombosis (Dales et al., 2010) there was little difference in the magnitude of associations between males and females.

Similarly, evidence does not indicate disparities in cardiovascular outcomes from long-term $PM_{2.5}$ exposure. As with short-term exposures, disparities may vary by the specific characteristics of the population. A study of the U.S. population as a whole found little difference in CVD mortality by sex (Thurston et al., 2015), yet a study focused on families in the agricultural sectors of Iowa and North Carolina found somewhat higher mortality risk in males (Weichenthal et al., 2014). In general, however, recent long-term $PM_{2.5}$ exposure studies show only minor differences in outcomes by sex for heart disease (Wong et al., 2015; Johnson and Parker, 2009), hypertension (Chen et al., 2014; Johnson and Parker,

2009), blood pressure (Fuks et al., 2011), and cardiovascular disease or cardio-metabolic disease in general (Crouse et al., 2015; Wong et al., 2015).

There is little evidence for disparities in respiratory outcomes between males and females from long-term $PM_{2.5}$ exposures. A study of 50−71 year-olds in the U.S. found only a minor increase in respiratory mortality for women compared to men (Thurston et al., 2015). Conversely, a meta-analysis of European studies found a minor increase in men compared to women (Dimakopoulou et al., 2014). Wong et al. (2015) found little evidence of effect modification by sex for respiratory outcomes in Hong Kong. For short-term $PM_{2.5}$ exposure, Bell et al. (2015) found somewhat increased association in females for respiratory hospital admissions overall as well as for respiratory tract infections specifically. Other studies have found only negligible differences between males and females for respiratory hospital admissions (Lanzinger et al., 2016; Liu et al., 2016; Rodopoulou et al., 2015), pediatric asthma (Gleason et al., 2014), and peak expiratory flow (Watanabe et al., 2015).

Overall, the evidence is inadequate to determine if males are at increased risk for $PM_{2.5}$-associated health effects compared to females. There is some evidence that males may have higher mortality risk due to long-term $PM_{2.5}$ exposure than females. However, for other health outcomes associated with long-term $PM_{2.5}$ exposure as well as for morbidities resulting from short-term $PM_{2.5}$ exposure, there is inconsistent evidence that either males or females are at higher risk. In considering this evidence, it is also important to note that certain health outcomes are sex-specific. For example, there is some evidence for effects related to gestation that apply only to females and are not represented in sex-stratified studies, but this evidence is also inconsistent.

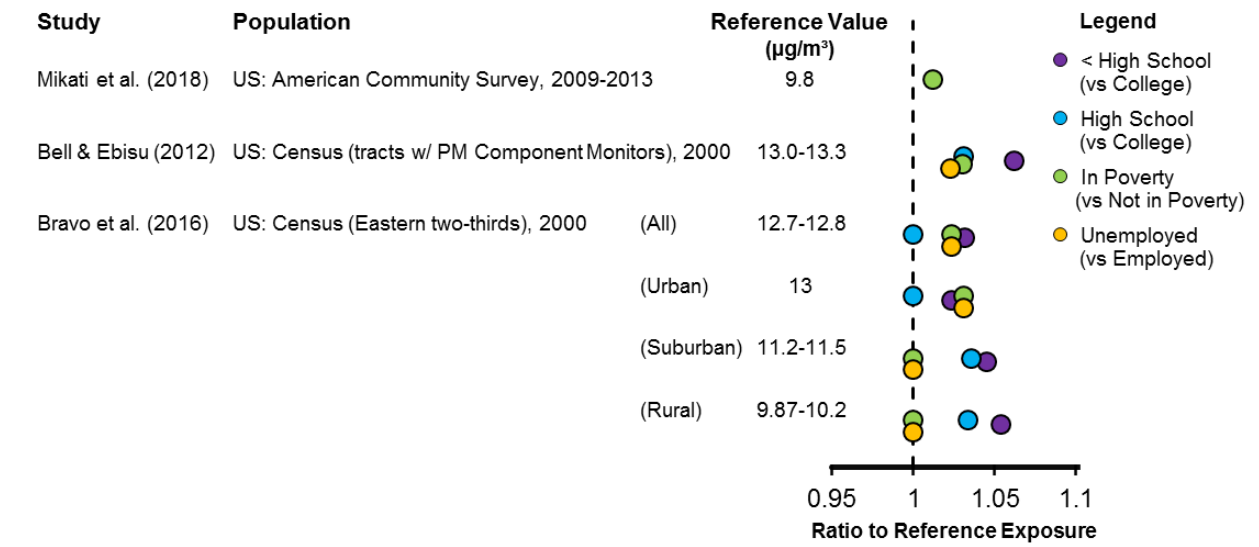
12.5.3 Socioeconomic Status

Overview

- Socioeconomic status (SES)—a composite measure that can include metrics such as income, education, or occupation—plays a role in access to healthy environments as well as access to healthcare in the U.S. Thus, SES may underlie differential risk for $PM_{2.5}$-related health effects.
- There is some evidence that demonstrates that having low income or living in lower-income areas results in stronger associations between mortality and long-term $PM_{2.5}$ exposures compared to higher-income counterparts.
- There is no clear pattern of differential risk when comparing effects in those with low educational attainment compared to higher educational attainment.
- **Taken together, the combination of exposure disparities and health evidence is suggestive that low SES populations are at increased risk for $PM_{2.5}$-related health effects compared to higher SES populations.**

Socioeconomic status (SES) is a composite measure that can represent various interrelated factors including income, education, or occupation—both in terms of the individual and in terms of the surrounding population's composition. The variety of metrics that fall under the umbrella of SES makes it difficult to make direct comparisons; for example, an income that is considered low in a particular city may be higher on the distribution of income at the national level. Furthermore, differences in social conditions from country to country make comparisons with studies taking place outside the U.S. difficult. However, it is still important to consider differential risk for $PM_{2.5}$-related health effects for SES. According to the U.S. Census Bureau, 12.7% of the U.S. population are living in poverty as of 2016 (Semega et al., 2017); 10.9% of the population aged 25 years and older does not have a high school diploma (U.S. Census Bureau, 2017a). Lower SES can impact place of residence and thus exposure to pollutants; it may be correlated with pre-existing health conditions that are potentially aggravated by air pollution; and it may result in inequities in access to resources such as healthcare.

Disparity in exposure to $PM_{2.5}$ due to differences in ambient $PM_{2.5}$ at the place of residence is one way in which SES may be related to PM risk (Figure 12-1). Mikati et al. (2018) compared modeled ambient $PM_{2.5}$ data for census tract populations across the U.S. and reported exposure to slightly higher concentrations of $PM_{2.5}$ for those living below the poverty line. Bell and Ebisu (2012) reported that those with less than a high school education, the unemployed, and those below the poverty line are exposed to higher concentrations of $PM_{2.5}$ (and to several $PM_{2.5}$ components) than do their higher-SES counterparts. Bravo et al. (2016) reported that lower educational attainment (no college degree) was associated with exposure to high $PM_{2.5}$ concentrations in suburban and rural areas (as well as urban areas when limiting to those without a high school diploma), and poverty status and unemployment were associated with exposure to high $PM_{2.5}$ concentrations in urban areas.



Note: Group for reference exposure listed in parentheses under legend.

Figure 12-1 Differences in $PM_{2.5}$ exposure by socioeconomic status (SES).

The 2009 PM ISA (U.S. EPA, 2009) found some evidence for increased risk of mortality due to short-term $PM_{2.5}$ exposure in low-SES individuals. More recent studies have added to our understanding of the relationship between SES and PM-related health effects., including evidence where a variety of SES metrics and categories have been simplified into "high," "medium," and "low" status.

Several studies examined differential risk for $PM_{2.5}$-related mortality by SES level (Supplemental Table S12-11) (U.S. EPA, 2018). An expansive study examining the association between long-term exposure to $PM_{2.5}$ and mortality in the cohort of all Medicare beneficiaries in the U.S. reported that low-SES individuals, as measured by Medicaid eligibility, had a higher risk of $PM_{2.5}$-related mortality than high-SES individuals (Di et al., 2017). Another pair of studies focusing on the Medicare population reported that those living in low-income neighborhoods or low-SES cities have a slightly higher risk of long-term $PM_{2.5}$-related mortality than those in higher-income neighborhoods or higher-SES cities (Wang et al., 2017; Kioumourtzoglou et al., 2016). Residents of low-SES ZIP codes have slightly higher risk of mortality from long-term PM exposure than residents of high-SES ZIP codes in the Eastern, Central, and Western U.S. (Zeger et al., 2008). Studies conducted in Canada have reported similar results (Crouse et al., 2015; Brook et al., 2013). Mortality outcomes from a study of short-term $PM_{2.5}$ exposure in Norway reported slightly decreased risk in low-SES areas compared to higher-SES areas (Madsen et al., 2012).

Studies focusing on educational attainment have reported mixed results. Lee et al. (2015) reported that the risk of mortality from short-term $PM_{2.5}$ for those in their study area of GA, NC, and SC was more than doubled in the group that had eight or fewer years of education compared to the group having more

than eight years of education. While at least one European study reported lower risk of $PM_{2.5}$-related mortality for low-education individuals (Beelen et al., 2014a), other studies in the U.S. have reported either negligible differences by education status (Thurston et al., 2015) or higher risk of $PM_{2.5}$-related mortality for lower-education individuals (Kloog et al., 2013).

There is little evidence that the effect of $PM_{2.5}$ exposure on cardiovascular health outcomes is modified by SES. Coogan et al. (2016) conducted an analysis focused on long-term $PM_{2.5}$ exposure in a cohort of black women; among this subset of the population, risk of hypertension as a result of $PM_{2.5}$ was somewhat more pronounced in women outside the highest quintile of neighborhood SES, raising the possibility that race and SES interact. Kloog et al. (2014) reported that the increase in hospital admissions from short-term $PM_{2.5}$ exposure was greater in low income groups than in high income groups; however, other studies reporting CVD effects for both short-term (Haley et al., 2009) and long-term exposure (Johnson and Parker, 2009) have not reported this to be the case. A German study on the effects of long-term $PM_{2.5}$ exposure on blood pressure found no increase in risk for the unemployed compared to the employed (Fuks et al., 2011).

Results of CVD studies using education attainment as a metric of SES have been inconsistent (Supplemental Table S12-10) (U.S. EPA, 2018). Thurston et al. (2015) reported little difference in long-term $PM_{2.5}$-related CVD mortality between those with less than a high school education and those with greater than a high school education. Those with exactly a high school level education, however, had somewhat higher associations than either of these two groups. Increased CVD risk within an intermediate educational group was also reported by Coogan et al. (2016) which showed that participants with some college education had higher risk of hypertension from long-term $PM_{2.5}$ exposure than did college graduates or those without any college education. Johnson and Parker (2009) reported slightly higher associations for heart disease and for hypertension from long-term $PM_{2.5}$ exposure in lower-education individuals. Studies outside the U.S. have not shown that lower education individuals are more at risk for cardiovascular outcomes (Chen et al., 2014; Fuks et al., 2011).

The evidence that SES modifies the association between respiratory morbidity from PM exposure is also weak. Multiple Atlanta-based studies examining short-term $PM_{2.5}$ exposure and asthma reported results including slightly higher odds of asthma attacks for those in high-poverty ZIP codes and for those who were eligible for Medicaid, as well as those with lower maternal educational attainment (O'Lenick et al., 2017; Strickland et al., 2014; Sarnat et al., 2013). Another study based in New Jersey found little distinction in outcomes between low, moderate, and high-SES participants (Gleason et al., 2014). Thurston et al. (2015) reported that long-term exposure and respiratory mortality were not more strongly associated for lower-education groups than for those with more than a high school education.

Taken together, the combination of exposure disparities and health evidence is suggestive that low SES populations are at increased risk for $PM_{2.5}$-related health effects compared to populations of higher SES. Several studies show increased risk of overall $PM_{2.5}$-related mortality for

lower-income groups, but the metrics for income vary widely across studies. In addition, there is also weak evidence for differential risk for $PM_{2.5}$-related outcomes by educational attainment.

12.5.4 Race

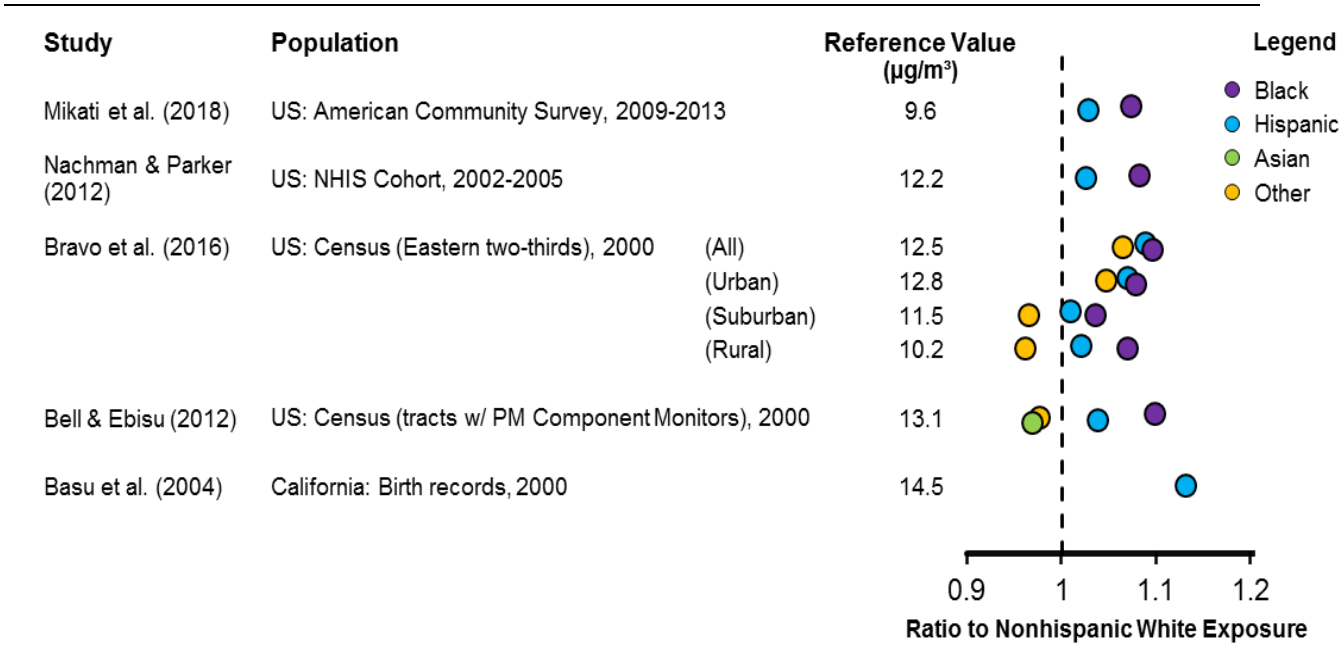
Overview

- People of different racial and ethnic backgrounds often have different health status disparities. The 2009 PM ISA found little evidence for increased $PM_{2.5}$-related risk by race and some evidence of increased risk by Hispanic ethnicity.
- Recent evidence demonstrates that there are consistent racial and ethnic disparities in $PM_{2.5}$ exposure across the U.S., particularly for blacks and African Americans compared to Nonhispanic whites.
- Recent studies provide evidence consistent with increased $PM_{2.5}$-related mortality from long-term exposure in blacks/African Americans; for $PM_{2.5}$-related health effects besides mortality there is also a general pattern of racial and ethnic disparities.
- **Overall, there is adequate evidence that race and ethnicity modify $PM_{2.5}$-related risk and that nonwhites, particularly Blacks, are at increased risk for $PM_{2.5}$-related health effects, in part due to disparities in exposure.**

Race and ethnicity are not biological categories but instead represent social definitions that broadly correspond to national origins (U.S. Census Bureau, 2017b). The U.S. Census Bureau considers racial categorization (e.g., white; black or African American; Hispanic; American Indian or Alaskan Native; Asian; Native Hawaiian or other Pacific Islander) to be distinct from ethnic categorization (e.g., Hispanic origin), but studies often examine race and ethnicity as a single concept (U.S. Census Bureau, 2017a). Furthermore, studies conducted outside of the U.S. may differ in the cultural and historical backgrounds that define race and ethnicity. Because of the fluidity of these categorizations, direct comparisons of results stratified by race and ethnicity between studies can be difficult. The evaluation of evidence for race and/or ethnicity in this section is done according to classifications made by original study authors.

The 2009 PM ISA (U.S. EPA, 2009) found little evidence that race and some evidence that ethnicity might be effect measure modifiers of PM-related mortality. However, this conclusion did not include an assessment of whether there is evidence of racial and ethnic disparities in PM exposure. Disparities in exposure to PM are one potential cause of disparity in PM-related health effects by race and ethnicity. Mikati et al. (2018) compared modeled ambient $PM_{2.5}$ data with census tract populations across the U.S. and reported higher exposures for Hispanics (9.9 $\mu g/m^3$) and higher exposures for Nonhispanic blacks (10.3 $\mu g/m^3$) than for Nonhispanic whites (9.6 $\mu g/m^3$). Nachman and Parker (2012) found that blacks in the nationally-representative 2002−2005 National Health Interview Survey were exposed to higher concentrations of ambient $PM_{2.5}$ (13.2 $\mu g/m^3$) than were Hispanics (12.5 $\mu g/m^3$) or Nonhispanic

whites (12.2 µg/m^3). Hispanics in this sample had only slightly higher exposures than Nonhispanic whites, but in some specific areas, the disparities may be larger. For example, a study of year 2000 birth records in the state of California reported a higher mean $PM_{2.5}$ concentration at monitors within five miles of Hispanic residences (18.2 µg/m^3) compared to Nonhispanic white (15.8 µg/m^3) residences over the gestation period (Basu et al., 2004). Disparities appear to persist in urban, suburban, and rural environments (Bravo et al., 2016). Hispanics and Blacks as well as Asians are also exposed to higher concentrations of certain components of $PM_{2.5}$ (such as elemental and organic carbon) than are Nonhispanic whites (Bell and Ebisu, 2012). In addition, Johnson and Parker (2009) reported that more blacks and Hispanics lived in high-exposure (≥15.8 µg/m^3) census block groups than whites.



Note: Group for reference exposure is Nonhispanic Whites.

Figure 12-2 Differences in $PM_{2.5}$ exposure by race.

A further limitation to the discussion of race in the 2009 PM ISA (U.S. EPA, 2009) was the small number of studies available at the time. For instance, evidence for modification of short-term $PM_{2.5}$ mortality risk by Hispanic ethnicity primarily came from two studies in California: Ostro et al. (2006) and Ostro et al. (2008). However, a number of studies published since the 2009 PM ISA have considered effect measure modification by race and ethnicity.

A number of epidemiologic studies that examined the association between long-term $PM_{2.5}$ exposure and mortality reported that race/ethnicity modifies this relationship (Supplemental Table S12-12) (U.S. EPA, 2018). There is evidence for elevated risk among Nonwhites compared to Whites. Kioumourtzoglou et al. (2016), (Wang et al., 2017), and (Arnaud, 2011) all examined long-term $PM_{2.5}$-related mortality in the U.S. Medicare population and found racial disparities in in mortality risk. Kioumourtzoglou et al. (2016) found higher long-term $PM_{2.5}$-related mortality among residents of cities at the 75th percentile of proportional black population than among those in cities at the 25th percentile. Di et al. (2017) observed that whites had a lower risk for long-term $PM_{2.5}$-related mortality (RR: 1.063; 95% CI: 1.060, 1.065) than the overall population while Hispanics (RR: 1.116; 95% CI: 1.100, 1.133) and Asians (RR: 1.096; 95% CI: 1.075, 1.117) had higher risk; blacks, meanwhile, had greater risk (RR: 1.208; 95% CI: 1.199, 1.217) than either of these groups. Furthermore, the researchers showed that this discrepancy was not explained by low economic status alone; blacks with a high enough income to be ineligible for Medicaid retained greater risk than Medicaid-eligible whites. However, within a 1997−2009 National Health Interview Survey cohort, Parker et al. (2017) did not find significant differences by race or ethnicity in all-cause or heart disease mortality. Wang et al. (2017), which focused on the Medicare population only in the Southeastern U.S., found a greater mortality risk from long-term $PM_{2.5}$ exposure for blacks than for whites in this region. A study focused only on mortality records in the states of Georgia, North Carolina, and South Carolina reported a greater increase in short-term $PM_{2.5}$-associated mortality among the black population as well (Lee et al., 2015).

Beyond studies of mortality, other recently published literature has examined whether there is evidence of effect measure modification by race/ethnicity on the relationship between long-term $PM_{2.5}$ exposure and cardiovascular effects. Johnson and Parker (2009) reported that only Hispanics had a significantly elevated risk for heart disease associated with long-term $PM_{2.5}$ exposure; only whites had a significantly elevated risk for hypertension.

Studies focused on smaller geographic areas have reported inconsistent results. Among the 2000−2002 Multiethnic Study of Atherosclerosis cohort recruited from six cities across the U.S., Hicken et al. (2016) observed a larger mean difference in left-ventricular mass index (an outcome related to hypertension) associated with long-term $PM_{2.5}$ exposure in Blacks as opposed to Whites. However, they did not report such a difference between groups for left-ventricular ejection fraction (another outcome related to hypertension). Similarly, a study of over 80,000 cases of cardiovascular-related ED visits in Central Arkansas did not find a significant racial difference in outcomes for short-term $PM_{2.5}$ exposures (Rodopoulou et al., 2015); nor did a study of transmural myocardial infarctions in New Jersey (Rich et al., 2010).

In addition, there is evidence that associations between $PM_{2.5}$ exposures and respiratory outcomes are stronger for nonwhites than whites. Nachman and Parker (2012) observed that asthma prevalence associated with long-term $PM_{2.5}$ exposure was statistically significantly higher in Nonhispanic blacks, but not in Hispanics, than in Nonhispanic. There is also some evidence of effect measure modification by race

for short-term $PM_{2.5}$ exposures and respiratory effects. Short-term $PM_{2.5}$-related respiratory risks focused on individual cities are inconsistent. Glad et al. (2012) observed a slight increase in odds of asthma ED visits for African Americans compared to whites associated with short-term $PM_{2.5}$ exposure in Allegheny County, PA from 2002−2005. Alhanti et al. (2016), on the other hand, investigated asthma-related ED visits in Atlanta, GA, Dallas, TX, and St. Louis, MO between 1993−2009 and did not observe pronounced differences between whites and nonwhites in associations with $PM_{2.5}$ either overall or within any specific age ranges or individual cities.

Strickland et al. (2014) focused on pediatric asthma in Atlanta from 2002−2010 and the relationship with a population-weighted city average for short-term $PM_{2.5}$ from several monitors. They observed higher risk associated with $PM_{2.5}$ on pediatric asthma ED visits for African Americans compared to non-African Americans, and this difference was more prominent than differences based on other measures such as education or Medicaid status. Gleason et al. (2014) focused on pediatric asthma ED visits in a 2005−2007 New Jersey cohort and did not find any significant difference in outcomes by black or white race, but did observe a significantly increased odds ratio of events in those of Hispanic ethnicity as opposed to Nonhispanic ethnicity. The Central Arkansas study by Rodopoulou et al. (2015) reported lower short-term $PM_{2.5}$-related risk of respiratory emergency room visits for African Americans.

While evidence for reproductive effects is only suggestive of, but not sufficient to infer, a causal relationship with exposure to PM2.5 (Chapter 9), a limited number of studies evaluated whether race/ethnicity modified the relationship between $PM_{2.5}$ exposure and reproductive outcomes, including adverse birth outcomes and maternal effects during pregnancy; they provide mixed evidence for greater risk among nonwhites. Bell et al. (2007) conducted a study of births in Massachusetts and Connecticut between 1999−2002, assigning $PM_{2.5}$ as the average of all monitors in a county. They noted a larger decrease in birthweight for black mothers than they did for white mothers. Pereira et al. (2014) overlapped with the time and geography of Bell et al. (2007) by considering preterm birth in Connecticut from 2000−2006. $PM_{2.5}$-related preterm birth was lower for children of white mothers (OR: 1.02; 95% CI: 0.88, 1.20) than for children of black mothers (OR: 1.39; 95% CI: 0.99, 1.96) or Hispanic mothers (OR: 1.31; 95% CI: 1.00, 1.73). Among Hispanic mothers, odds of preterm birth were uniquely high for $PM_{2.5}$ exposure within the first trimester (OR: 1.25; 95% CI: 1.08, 1.44). Green et al. (2015) modeled zip code-level $PM_{2.5}$ exposure in California from 1999−2009 and compared to over 5.5 million birth records in the state. They did not find differential effects for stillbirth by race or ethnicity. Vinikoor-Imler et al. (2012) analyzed the risk of gestational hypertension associated with $PM_{2.5}$ exposure in North Carolina between 2000−2003. They reported a significantly lower risk of gestational hypertension for Hispanics than for whites, but a significantly higher risk for blacks.

Overall, there is adequate evidence that nonwhites, particularly blacks, are at increased risk for $PM_{2.5}$-related health effects based on studies examining differential exposure and health effects. There is strong evidence demonstrating that black and Hispanic populations, in particular, have higher $PM_{2.5}$ exposures than Nonhispanic white populations. In addition, there is consistent evidence across

multiple studies demonstrating an increase in risk for Nonwhite populations. More specifically, effect measure modification by race in high-quality studies of $PM_{2.5}$-associated mortality (Di et al., 2017; Wang et al., 2017) are complemented by studies examining effect modification on $PM_{2.5}$-associated morbidity.

12.5.5 Residential Location

Overview

- New methods in exposure assessment allow for the estimation of $PM_{2.5}$ exposures for both urban and rural populations, evidence indicates that $PM_{2.5}$ is generally lower in rural areas compared to urban areas.
- Studies examining exposure differences in populations with close proximity to roadways indicate $PM_{2.5}$ concentrations are generally not elevated close to roadways.
- Evidence is inconsistent across stratified epidemiologic analyses examining health effects compared to degree of urbanicity (e.g., urban or rural residence).
- There is some evidence from epidemiologic and toxicological studies that demonstrates an increase in risk for those exposed to traffic particles or live near a roadway.
- With fewer available $PM_{2.5}$ monitor sites in smaller metropolitan and rural locations compared to larger metropolitan areas, the ability to validate modeled ambient $PM_{2.5}$ in less populated locations remains an important limitation; furthermore, the diversity in residential classification metrics limits the ability to interpret trends across studies.
- **Overall, the evidence is inadequate to determine if residential location increases risk for $PM_{2.5}$-related health effects.**

12.5.5.1 Urban/Rural Residential Locations

Many studies examining the health effects of $PM_{2.5}$ exposure have traditionally focused on urban populations due to the predominantly urban siting of monitors in the national monitoring network; however, those living outside major metropolitan areas may be exposed to different mixtures of particulate matter than those in urban areas (Xu et al., 2015) and this may vary across regions in the U.S. (Sections 2.5.3 and 3.4.4.1). Residential location may also be an important surrogate for other factors, including differing access to services, lifestyle, and other environmental exposures that could potentially influence $PM_{2.5}$-health associations (Grabich et al., 2016). Recent developments in estimating exposure through hybrid models drawing from satellite observations, chemical transport model output, and ambient concentration measurements to estimate ambient $PM_{2.5}$ concentrations have enabled a greater proportion of rural populations to be included in recent epidemiologic studies (Section. 3.3.2). These studies have not only examined whether overall associations between $PM_{2.5}$ and health outcomes are present with the addition of rural populations, but have also examined differences in associations between urban and rural populations. These new methods also provide the opportunity to examine if there are differences in associations by degree of urban density or urbanicity, as many previous studies relied on a limited number of fixed site monitors in large metropolitan areas.

Few studies in the 2009 PM ISA reviewed the potential for modification by residential location, and those that did often incorporated residential information only as a general surrogate for socioeconomic status. However, a study in Phoenix did note that the largest association between mortality and short-term $PM_{2.5}$ exposure was in an area of medium urban density in central Phoenix (Wilson et al., 2007). Recent studies have examined whether degree of urbanicity modifies the association between $PM_{2.5}$ exposure and a variety of health effects. These studies report inconsistent results with the majority of studies focusing on mortality and long-term $PM_{2.5}$ exposure.

$PM_{2.5}$ concentrations are generally lower in rural areas compared to urban areas in the U.S., based both on limited monitoring data, as well as remote-sensing and hybrid modeled $PM_{2.5}$ estimates (Section 2.5.3). Several epidemiologic studies reported average $PM_{2.5}$ stratified by varying definitions of urban and rural residential location and generally observed similar trends of lower $PM_{2.5}$ in rural areas. Average annual rural $PM_{2.5}$ in the U.S. ranged from 10.2−12.9 $\mu g/m^3$, while urban $PM_{2.5}$ ranged from 11.5−15.5 $\mu g/m^3$ (Bravo et al., 2017; Garcia et al., 2015; Strickland et al., 2015). Moreover, there are compositional characteristics of urban ambient $PM_{2.5}$ that are consistent with traffic emissions and have been shown to change when moving away from the urban center (Section 2.5.1.2.5).

There is some evidence of stronger associations between $PM_{2.5}$ exposure and mortality in urban areas compared to rural areas; however, evidence is inconsistent across various metrics that use different categorization schemes based on the population size of a city or city urbanicity (Supplemental Table S12-13) (U.S. EPA, 2018). Di et al. (2017) and Kioumourtzoglou et al. (2016) both examined long-term $PM_{2.5}$ exposure and mortality using nationwide Medicare data, though the latter focused on the variation of urbanicity, rather than a comparison to nonmetropolitan areas.. Using modeled $PM_{2.5}$ across the entire continental U.S., as well as the largest Medicare study population to date, Di et al. (2017) observed stronger positive associations between $PM_{2.5}$ exposure and mortality in areas of moderate population density compared to areas of high population density. Meanwhile, Di et al. (2017) observed a smaller positive association among areas of low population density. Kioumourtzoglou et al. (2016) observed no strong evidence of modification in a pooled analysis of 207 U.S. cities by degree of urbanicity or population density within cities. However, in region specific metaregression the authors observed that as population density and urbanicity increased, there were larger effects for $PM_{2.5}$-mortality in the Northeast, Midwest, and Northwest compared to the South, Southeast, Central, Southwest, and Western regions of the U.S.

Additional multicity studies in the U.S, including six Northeastern states (Shi et al., 2015), seven Southeastern states (Wang et al., 2017), and Massachusetts (Kloog et al., 2013) also used hybrid models to estimate long-term $PM_{2.5}$ exposure and observed some evidence of decreased risk of mortality in rural populations compared to urban populations. This difference in effect also persisted in models simultaneously stratified by race and sex (Wang et al., 2017). Conversely, a study of diabetes-related mortality and long-term $PM_{2.5}$ exposure in Canada observed a larger, but imprecise (i.e., wide 95% confidence intervals), association in rural areas compared to large or mid-population cities (Brook et al.,

2013). A study in California also observed higher rates of cardiovascular, cardiopulmonary, and overall mortality in rural compared to urban zip codes, though the strength of this pattern varied substantially by $PM_{2.5}$ exposure assignment method (Garcia et al., 2015). In addition to studies of long-term $PM_{2.5}$ exposure, a study of mortality and short-term $PM_{2.5}$ exposure in Georgia, North Carolina, and South Carolina observed higher risks in rural zip codes compared to metropolitan urban cores (Lee et al., 2015).

A limited number of studies evaluated if urbanicity characteristics modified the association between other health effects and $PM_{2.5}$, such as cardiovascular effects, respiratory effects and reproductive outcomes. In a study of long-term $PM_{2.5}$ exposure, Johnson and Parker (2009) observed attenuated associations in less-urban areas for self-reported cardiovascular disease, but larger associations for self-reported hypertension in urban areas.

Among a limited number of studies for short-term $PM_{2.5}$ exposure, studies of cardiovascular effects were inconsistent, while studies of respiratory effects tended to see increasing risk in less urban areas. Kloog et al. (2014) observed a negative association in urban areas, and no association in rural areas using Medicare data on cardiovascular hospital admissions. Conversely, using Medicare data in 708 U.S. counties, Bravo et al. (2017) reported increasing associations between short-term $PM_{2.5}$ exposure and cardiovascular hospitalization in more urban areas, though larger associations in less urban areas for respiratory hospital admissions. In the state of Georgia, Strickland et al. (2015) observed positive associations in less urban areas compared to null or negative associations in large metropolitan areas for less frequent respiratory hospital admissions, such as bronchitis, pneumonia, and sinusitis, though estimates were imprecise (i.e., wide 95% confidence intervals). Among more frequent respiratory outcomes, such as asthma, there was less evidence of effect modification. In contrast to other studies of respiratory outcomes, there was a trend of stronger associations for respiratory hospital admissions in urban areas in Southern California, compared to less urban counties in the Central Valley (Yap et al., 2013).

In studies of reproductive outcomes, Hu et al. (2015) observed an increased risk of gestational diabetes in Florida for mothers in rural areas. Meanwhile, in a nationwide study of infant births in Canada, Stieb et al. (2015) observed no substantial evidence of modification by maternal residential status. However, the authors observed small increases in rural births at risk for small for gestational age, as well as a decline in term birthweight.

12.5.5.2 Residential Proximity to Traffic

Traffic-related air pollution is a complex mixture typically consisting of both particulate and gaseous pollutants. Elevated near-road concentrations of UFP have been observed, although measured $PM_{2.5}$ concentrations are generally not elevated near the road (Karner et al., 2010), given that most $PM_{2.5}$ is produced via atmospheric chemistry. Both traffic-related air and noise pollution have been hypothesized to be associated with detrimental health effects; however, few studies have examined if

residential traffic proximity modifies existing associations between short- and long-term $PM_{2.5}$ exposure and health effects. No studies examined residential proximity to traffic in the 2009 PM ISA, though one study did suggest urban areas of low SES were disproportionately exposed to traffic-related pollutants (Yanosky et al., 2008).

Recent epidemiologic studies provide limited evidence that those living close to major roadways may be at greater risk for $PM_{2.5}$ associated cardiovascular or respiratory effects compared to those living farther from major roadways. In a study of short-term $PM_{2.5}$ exposure using data from the multicity MESA cohort, Auchincloss et al. (2008) observed stronger positive associations with pulse pressure and systolic blood pressure among those living within 300 meters of highways compared to those living further from highways, as well as positive associations for those in areas of higher road density. Smaller studies also observed stronger associations with $PM_{2.5}$ among residents living close to major roadways; however, the evaluated distance from roadways varied. In Atlanta, Georgia Sinclair et al. (2014) observed higher risk for $PM_{2.5}$-related asthma pediatric primary care visits among residents within 150 meters of major roadways, though not at 300 meters. Among stroke hospitalizations in southern Israel, Yitshak Sade et al. (2015) observed an increased risk of ischemic stroke for those living within 75 meters from main roads (OR: 1.42, 95% CI: 1.06, 1.87) compared to those further than 75 meters away (OR: 1.06, 95% CI: 0.89, 1.27).

A limited number of animal toxicology studies also support the importance of proximity to PM source. In Los Angeles, the enhancement of allergic responses was greater in allergic BALB/c mice exposed to $PM_{2.5}$ CAPs (multiday, 400 $\mu g/m^3$) 50 m from a busy roadway compared to those at a distance of 150 m (Kleinman et al., 2005). Additionally, a single acute exposure to aerosolized diesel exhaust particles resulted in increased BALF IL-4 levels in OVA-sensitized/challenged mice at exposures of 2000 $\mu g/m^3$, but not 870 $\mu g/m^3$ (Farraj et al., 2006a, b).

Summary

Overall, there is inadequate evidence to determine if residential location, either close proximity to a roadway or in a rural or urban area, increases risk for $PM_{2.5}$-related health effects. There is evidence that degree of urbanicity may modify the risk of $PM_{2.5}$-related health effects, particularly from large nationwide studies of mortality and long-term $PM_{2.5}$ exposure; however, in contrast to studies of mortality, several cardiovascular, respiratory, reproductive, and developmental studies observed limited evidence of increased risk in rural areas compared to urban areas. There may also be differences between metro areas of different sizes, though interpreting these trends is limited by the varying definition of urbanicity across studies. Furthermore, despite recent developments in methods to estimate ambient $PM_{2.5}$ concentrations, the limited availability of monitored data in smaller metropolitan and rural locations to validate modeled ambient $PM_{2.5}$ remains an important limitation (Sections 3.3.2, 3.3.3, 3.4.2.4). A limited number of epidemiologic studies also provide some evidence of stronger $PM_{2.5}$ related effects for those living closer to major roadways for asthma, stroke, and elevated

blood pressure compared to those living further from roadways. The available animal toxicology studies also suggest elevated immune responses among mice exposed to traffic-related exhaust. However, there is insufficient information available to determine how far these effects may extend from roadways, and if the relevant distances vary by health outcome, or other factors, such as levels of noise pollution.

12.6 Behavioral and Other Factors

12.6.1 Smoking

Overview

- It is unclear whether smoking exacerbates health effects associated with air pollutant exposures, including PM, and the potential for this was not evaluated in the 2009 PM ISA.
- Recent evidence does not indicate that smoking modifies the effect of long-term $PM_{2.5}$ exposures on cardiovascular disease or mortality; evidence evaluating differential effects by smoking status is limited for short-term $PM_{2.5}$ exposures.
- **Overall, the evidence is inadequate to determine whether individuals who smoke are at increased risk of $PM_{2.5}$-related health effects compared to those that do not smoke.**

Smoking is a common behavior as indicated by the 2016 National Health Interview Survey which estimated that within the U.S. adult population approximately 15.5% of individuals report being current smokers and 21.5% report being a former smoker (Blackwell and Villarroel, 2018). Smoking is a well-documented risk factor for many diseases, but it is unclear whether smoking exacerbates health effects associated with air pollutant exposures, including PM.

A number of studies have evaluated whether smoking status modifies the relationship between $PM_{2.5}$ exposure and health effects. The majority of these studies examined the relationship between long-term $PM_{2.5}$ exposure and mortality or cardiovascular morbidity. Generally, little difference is observed in the relationship between long-term exposure to $PM_{2.5}$ and mortality or cardiovascular morbidity when examined by smoking status. When differences in the relationship do occur, there is no consistent pattern or trend that support current, former, or ever smokers (i.e., both current and former smokers) being at increased or decreased risk than never smokers for these health outcomes. In a reanalysis of the ACS cohort, Turner et al. (2017) evaluated the interaction between $PM_{2.5}$ exposure and smoking, stratifying $PM_{2.5}$ exposure into low (<10.59 $\mu g/m^3$) and high (>14.44 $\mu g/m^3$) categories. These authors observed positive associations between higher $PM_{2.5}$ exposures and both total and CVD mortality; the interaction between current smoking and high $PM_{2.5}$ exposure increased the risk by 10%. In addition to the mortality and cardiovascular effects, several studies examined the ability of smoking status to modify the relationship between long-term $PM_{2.5}$ exposure and changes in blood pressure (Chan et al.,

2015; Mu et al., 2014; Fuks et al., 2011; Auchincloss et al., 2008) and indicators of atherosclerosis (Bauer et al., 2010; Lenters et al., 2010) and observed no consistent pattern among any smoking strata.

A smaller number of studies examined smoking status as a potential modifier of the effect of short-term $PM_{2.5}$ exposure on health outcomes (Supplemental Table S12-14) (U.S. EPA, 2018). A multicity analysis of mortality observed higher effects of $PM_{2.5}$ in counties where the prevalence of smoking was higher, but lacked individual-level smoking data (Dai et al., 2014). O'Donnell et al. (2011) examined whether the relationship between short-term $PM_{2.5}$ exposure and ischemic stroke differed by smoking status of participants and observed no evidence that smoking modified this relationship.

Overall, the inconsistent evidence is inadequate to determine whether individuals who smoke are at increased risk of $PM_{2.5}$-related health effects compared to those that do not smoke. A number of long-term exposure studies observed a mix of positive or nearly null associations for mortality and cardiovascular morbidity endpoints, but no clear or consistent trend is apparent among current, former, or ever smokers when compared to never smokers. Fewer studies evaluated smoking as an effect modifier of the relationship between short-term $PM_{2.5}$ exposure and health outcomes, and one study observed a stronger $PM_{2.5}$-mortality relationship in counties with a higher prevalence of smoking, but no individual-level data were available. Additionally, the varied metrics used to define smoking across studies (e.g., current, former, quantity) is a particular uncertainty in this evidence base.

12.6.2 Diet

Overview

- Dietary habits are well-established risk factors for metabolic/cardiovascular conditions that may be associated with $PM_{2.5}$ exposure; diet is an important source of anti-inflammatory and antioxidant compounds that may alter early biological responses to $PM_{2.5}$.
- Limited stratified epidemiologic analyses of alcohol or fruit and vegetable consumption do not indicate differences in mortality and $PM_{2.5}$ exposure.
- Limited evidence from controlled human exposure studies in the current and previous ISA demonstrates reduced cardiovascular and inflammatory responses among those taking B vitamin supplements
- **Overall, the evidence is inadequate to determine whether dietary patterns modify $PM_{2.5}$-related health effects.**

Dietary habits are well established risk factors for a variety of health outcomes, in particular, the development of metabolic-related conditions that may simultaneously be associated with PM exposure (Cardiovascular Effects, Section 6.2.1 and Section 6.3.1; Metabolic Effects, Section 7.2.1). It is possible that as dietary habits influence the development of chronic disease, there are increased risks of other $PM_{2.5}$-health effects for those with cardiovascular disease (Section 12.3.1), diabetes (Section 12.3.2), and

obesity (Section 12.3.3). Dietary tendencies also differ across the U.S. population, for example, low socioeconomic status (SES) individuals may have limited access to fresh foods (Larson et al., 2009). Limited access to fresh foods may lead to reduced intake of anti-inflammatory compounds and antioxidant polyunsaturated fatty acids and vitamins, which has been hypothesized to increase a population's risk of developing a PM-related health effect (Romieu et al., 2005).

The 2009 PM ISA concluded that nutritional status, among other surrogates of SES, may modify the association between PM and various health outcomes. Evidence for this conclusion was largely based a single study that examined $PM_{2.5}$ exposure and heart-rate variability (HRV) by nutritional status among those with genetic predisposition for cardiovascular disease (Baccarelli et al., 2008). The authors found that when individuals with genetic polymorphisms increased their consumption of B vitamins or methionine, they no longer observed an association between $PM_{2.5}$ and HRV. More recently, several studies have evaluated the ability of alcohol, fruit and vegetable consumption, and fatty acid supplementation to modify associations between $PM_{2.5}$ exposure and health outcomes in populations beyond those with specific genetic polymorphisms, primarily for long-term $PM_{2.5}$ exposure and mortality. While some studies observed differential effects, there is little consistency across studies, and effect estimates were often imprecise (i.e., wide 95% confidence intervals) (Supplemental Table S12-15) (U.S. EPA, 2018).

A limited number of epidemiologic studies evaluated effect measure modification by alcohol consumption. In a study of the Canadian Community Health Survey cohort, Pinault et al. (2016) examined associations between mortality and long-term $PM_{2.5}$ exposure and observed little evidence of differences based on regular drinking status for all-cause, cardiovascular, or respiratory mortality. In a study of long-term $PM_{2.5}$ exposure and systemic inflammation among mid-life women, Ostro et al. (2014) also observed little difference in C-reactive protein changes between abstainers and occasional consumers of alcohol. However, in a subanalysis examining the probability of a clinically relevant level of CRP (3 mg/l), the authors observed a positive association in older women who abstained from alcohol compared to a null association among older women who were occasional drinkers.

Several epidemiologic studies that examined the association between mortality and long-term $PM_{2.5}$ exposure evaluated potential modification by fruit and/or vegetable consumption patterns. Overall, few differences in mortality were observed when results were stratified by dietary patterns, and there is no consistent pattern to support greater fruit and vegetable consumptions leads to differential risk compared to lower fruit and vegetable consumption. U.S. based studies of cardiovascular mortality (Pope et al., 2014) and lung cancer mortality (Turner et al., 2011) did not observe a consistent pattern of differential risk by diet. Results stratified by quartile of fat consumption showed a similar pattern as when stratifying by fruit and vegetable consumption (Pope et al., 2014). Using data from the Canadian Community Health Survey cohort, Pinault et al. (2016) observed similar inconsistencies by mortality type, where the risk of $PM_{2.5}$ associated mortality slightly increased, or decreased depending on mortality categorization for the group consuming at least five or more servings of vegetables and fruit per day. Likewise, in a pooled

analysis of mortality and long-term $PM_{2.5}$ exposure across European cohorts (ESCAPE), no consistent pattern was observed between groups based on estimated grams of fruit consumed per day for all-cause, cardiovascular mortality, or respiratory mortality (Beelen et al., 2014a; Beelen et al., 2014b; Dimakopoulou et al., 2014).

The 2009 PM ISA examined a single study on nutritional status, which observed B vitamin supplementation attenuated the association between $PM_{2.5}$ and HRV among individuals with specific genetic polymorphisms that are associated with increased cardiovascular risk (Baccarelli et al., 2008). A recent pilot crossover study using 2 hour CAPS exposures examined B vitamin supplementation in a more general population and continues to provide limited evidence that B vitamins may protect against subclinical cardiovascular and inflammatory responses. Zhong et al. (2017a) observed attenuation in effects for measure of HRV and inflammatory blood markers, while using the same study population Zhong et al. (2017b) observed attenuated effects for DNA methylation and mitochondrial DNA content following vitamin B supplementation.

Controlled human exposure studies among the elderly have also examined the role of fish and olive oil supplementation and provide limited evidence that these oils may protect against certain subclinical responses to short-term $PM_{2.5}$ CAPs exposure. A series of CAPs studies in Chapel Hill, North Carolina provided olive oil (OO) or fish oil (FO) supplements to participants for four weeks, and then examined cardiovascular responses after two hours of CAPs exposure (Section 6.2.6, Table 6-12 and Section 6.2.4, Table 6-9). Tong et al. (2015) observed larger changes in endothelial function (i.e., decreased flow-mediated dilation) in the FO and nonsupplemented groups compared to the OO group, as well as increased vasoconstrictor concentrations (i.e., endothelin-1) for the nonsupplemented group. Results of fibrinolysis were less consistent, with increased tissue plasminogen activator, but decreases D-dimer levels after 20 hours in the OO group, but not FO or nonsupplemented group. In examining electrophysiological responses, Tong et al. (2012) did not include a nonoil supplement group, though the authors observed decreased responses to CAP exposure for heart rate variability, QT repolarization, and some blood lipids, such as VLDL and triglycerides, among those using FO compared to those using OO.

Overall, there is inadequate evidence to determine whether dietary patterns modify $PM_{2.5}$-associated health effects. Based on the limited number of epidemiologic studies, there is little evidence of differences in the relationship between mortality and $PM_{2.5}$ based on either alcohol or fruit and vegetable consumption. However, controlled human exposure studies of B vitamin, fish, and olive oil supplementation suggest potential protective effects against short-term exposure to concentrated ambient particles. Among epidemiologic studies, the reliance on long-term mortality studies is an important limitation, as self-reporting biases may still be problematic in accurate collection of dietary habits.

12.7 Conclusions

This chapter characterized the evidence for factors that may result in populations and lifestages being at increased risk for $PM_{2.5}$-related health effects (Table 12-3). The evaluation of each factor focused on the consistency, coherence, and biological plausibility of evidence integrated across a range of scientific disciplines informing whether a specific population or lifestage might be at increased risk of a PM-related health effect using the systematic framework detailed in Table 12-1. In the evaluation and characterization of the evidence consideration was given to exposure, dosimetry, biological plausibility, and/or the relationships of PM exposure with health effects as evaluated in Chapters 5-11 of this ISA. As noted in the introduction to this chapter, the 2009 PM ISA focused broadly on the extent to which evidence indicated that certain populations or lifestages were "susceptible" to PM-related health effects, but more recent ISAs have applied the systematic framework so the evaluation and conclusions in this ISA are more nuanced. Table 12-3 presents a summary of the conclusions and evidence evaluated and integrated in this chapter for each factor potentially resulting in an increase in risk for a $PM_{2.5}$-related health effect.

Of the factors considered, race and lifestage (children) were the only factors for which evidence was adequate to indicate an increase in risk for $PM_{2.5}$-related health effects (Section 12.5.4 and Section 12.5.1.1). In particular, evidence for both health effects, primarily mortality, and exposure demonstrate that nonwhite populations are at increased risk compared to whites. Several high-quality studies indicate that nonwhite populations across different geographical regions are exposed to higher concentrations of $PM_{2.5}$. In addition, a number of high-quality epidemiologic studies demonstrate stronger associations in nonwhite populations for $PM_{2.5}$-associated mortality. Increased risk for nonwhites compared to whites has also been demonstrated for other health outcomes including respiratory and cardiovascular effects and birth outcomes, but there is less confidence in the evidence for these outcomes.

There is strong evidence from studies examining health endpoints specific to children indicating that children are at increased risk to the effects of $PM_{2.5}$ exposure. Specifically, epidemiologic studies of long-term $PM_{2.5}$ exposure demonstrate associations with impaired lung function growth (Section 5.2.2.1.1), decrements in lung function (Section 5.2.2.2.1), and increased incidence of asthma development in children (Section 5.2.3.1). The evidence from stratified analyses provides limited direct evidence that children are at increased risk of $PM_{2.5}$-related health effects compared to adults. In addition, there is some evidence indicating that children can have higher $PM_{2.5}$ exposures than adults and that there are dosimetric differences in children compared to adults that can contribute to higher doses.

There is suggestive evidence that populations with pre-existing cardiovascular or respiratory disease (Section 12.3.1 and Section 12.3.5), populations that are overweight or obese (Section 12.3.3), populations that have particular genetic variants (Section 12.4), or populations that are of low SES (Section 12.5.3) are at increased-risk for $PM_{2.5}$-related health effects compared to respective reference populations. While stratified analyses for pre-existing cardiovascular disease do not consistently indicate

differential risk, there is some evidence that those with hypertension may be at increased risk compared to those without hypertension. In addition, there is strong evidence supporting a causal relationship between exposure to $PM_{2.5}$ and cardiovascular health effects, particularly mortality and ischemic heart disease (Chapter 6), and those with underlying cardiovascular conditions related to these serious outcomes may be at increased risk based on pathophysiological considerations compared to those without these conditions. Similarly, for pre-existing respiratory disease, evidence is limited that directly informs differential risk between those with and without pre-existing respiratory disease. However, Chapter 5 concluded that there is likely to be a causal relationship between short-term $PM_{2.5}$ exposure and respiratory effects, based primarily on evidence for exacerbation of asthma and COPD. Those with pre-existing obesity may also be at increased risk compared to those of healthy weight, based on evidence indicating greater risk for mortality associated with long-term exposures to $PM_{2.5}$ in individuals who are obese or overweight compared to those who are normal weight. In considering the evidence for genetic background, a variety of gene variants have been studied. There is a consistent trend for increased risk for respiratory and cardiovascular effects associated with $PM_{2.5}$ across gene variants involved in the glutathione pathway and oxidant metabolism, which is consistent with biological plausibility indicating that oxidative stress is an early biological response to $PM_{2.5}$ exposure. Evidence for other genetic variants is very limited. Finally, evidence indicates that those that are of low SES are more likely to have higher $PM_{2.5}$ exposures and that low SES, as measured by metrics for income, may increase risk for $PM_{2.5}$-associated mortality compared to higher SES categories, though there is some inconsistency in the evidence and heterogeneity in the metrics used.

There is inadequate evidence to determine whether pre-existing diabetes (Section 12.3.2), elevated cholesterol (Section 12.3.4), lifestage: older adults (Section 12.5.1.2), residential location (including proximity to source and urban residence [Section 12.5.5], sex [Section 12.5.2], or diet [Section 12.6.2]) modify risk for $PM_{2.5}$-associated health effects. For lifestage related to older adults (Section 12.5.1.2) there is limited evidence indicating that older adults are at increased risk for $PM_{2.5}$-related health effects; however, epidemiologic panel studies and controlled human exposure studies of older adults provide some evidence that subclinical cardiovascular outcomes are associated with short-term exposure to $PM_{2.5}$ for this lifestage. Evidence for other factors is inadequate due to limited evidence (residential patterns, diet) or inconsistency across the available evidence (diabetes and sex).

Table 12-3 Summary of evidence for populations potentially at increased risk of $PM_{2.5}$-related health effects.

Evidence Classification	Factor Evaluated	Population/Lifestage Potentially at Increased Risk	Factor-specific Evidence	Evidence Informing an Increase in Risk
Adequate Evidence	Race (Section 12.5.4)	Nonwhite populations		Evidence from multiple high-quality studies demonstrating higher $PM_{2.5}$ exposure in nonwhite populations. Consistent evidence from high quality studies demonstrating increased risk for mortality and cardiovascular/respiratory morbidity.
	Lifestage	Children (Section 12.5.1.1)	Strong evidence demonstrating health effects in children, particularly from epidemiologic studies of long-term $PM_{2.5}$ exposure and impaired lung function growth, decrements in lung function, and asthma development.	Limited evidence from stratified analyses to inform increased risk in children compared to adults. However, evidence from studies of pediatric asthma and impaired lung development provide strong and consistent evidence that effects are observed in children.
Suggestive Evidence	Pre-existing Disease	Pre-existing Cardiovascular Disease (Section 12.3.1)	Causal relationship for $PM_{2.5}$ exposure and cardiovascular effects based on CV mortality and morbidities that are plausibly more prevalent in those with pre-existing CV disease/conditions.	Generally supportive evidence from epidemiologic studies demonstrating differential effects for those with hypertension. Limited and inconsistent evidence for other pre-existing cardiovascular diseases.
		Pre-existing Respiratory Disease (Section 12.3.5)	Likely to be causal relationship for short-term $PM_{2.5}$ exposure and respiratory effects based primarily on evidence for asthma and COPD exacerbation. Evaluated outcomes are often specific to those with asthma or COPD and those without asthma or COPD are not included for comparison.	Limited evidence. Primarily cardiovascular outcomes in epidemiologic studies. Although asthma exacerbation is a key outcome for conclusions on respiratory effects, no informs an increase in risk for those with asthma compared to those without. There is very limited evidence for COPD.

Table 12-3 (Continued): Summary of evidence for potential increased risk of $PM_{2.5}$-related health effects

Evidence Classification	Factor Evaluated	Population/Lifestage Potentially at Increased Risk	Factor-specific Evidence	Evidence Informing an Increase in Risk
Suggestive Evidence (continued)	Pre-existing Disease (continued)	Obesity (Section 12.3.3)		Based primarily on evidence for increased risk for mortality with supporting evidence from studies of subclinical cardiovascular outcomes.
	Genetic background (Section 12.4)	Individuals with variant genotypes	Biological plausibility for $PM_{2.5}$-associated health effects is based on biological pathways including oxidative stress as early biological responses upon exposure to $PM_{2.5}$.	Generally consistent evidence for increased risk for respiratory and cardiovascular outcomes for genetic variants in the glutathione pathway, which has an important role in oxidative stress. Limited evidence for other genetic variants.
Suggestive Evidence (Continued)	Socioeconomic Status (Section 12.5.3)	Low socioeconomic status		Evidence demonstrates increased exposure and some evidence for stronger associations for mortality with low SES. Comparison across SES metrics are a limitation.
Inadequate Evidence	Pre-existing disease	Pre-existing diabetes		Inconsistent evidence across studies of mortality, cardiovascular morbidity, and inflammation.
	Lifestage	Older adults (Section 12.5.1.2)	Evidence demonstrating health effects in older adults, particularly from short- and long-term $PM_{2.5}$ exposure and cardiovascular or respiratory hospital admission, emergency department visits, or mortality.	Inconsistent evidence across a large body of studies with stratified analyses.
	Residential location (Section 12.5.5)	Near-road or urban residence		Some evidence demonstrates potential for urbanicity to modify $PM_{2.5}$-related health effects, but results are inconsistent across the broad range of metrics used.
	Sex (Section 12.5.2)	Males[a]	Males: Reproductive factors e.g., sperm motility. Females: Gestation and birth outcomes.	Inconsistent evidence across studies for mortality and cardiovascular and respiratory effects.

Table 12-3 (Continued): Summary of evidence for potential increased risk of $PM_{2.5}$-related health effects

Evidence Classification	Factor Evaluated	Population/Lifestage Potentially at Increased Risk	Factor-specific Evidence	Evidence Informing an Increase in Risk
Inadequate Evidence (continued)	Smoking (Section 12.6.1)	Current smoking		Inconsistent evidence for modification of associations between $PM_{2.5}$ and mortality, cardiovascular, reproductive, metabolic, and reproductive outcomes.
Inadequate Evidence (Continued)	Diet (Section 12.6.2)	Individuals with reduced fruit/vegetable intake, alcohol consumption, or elevated cholesterol		Inconsistent evidence across a limited evidence base.
Evidence of no effect	None			

ISA = Integrated Science Assessment.

Males selected as potential at-risk group due to shorter life-span. The use of males or females as the reference/comparison group does not change the evaluation of evidence in determining differential risk.

CHAPTER 13 WELFARE EFFECTS

Summary of Causality Determinations for Particulate Matter (PM) and Welfare Effects

This chapter characterizes the scientific evidence that supports causality determinations for PM exposure and nonecological welfare effects. The types of studies evaluated within this chapter are consistent with the overall scope of the ISA as detailed in the Preface (see Section P.3.1). More details on the causal framework used to reach these conclusions are included in the Preamble to the ISA (U.S. EPA, 2015).

Effect	Causality Determination
Visibility	Causal
Climate	Causal
Materials	Causal

13.1 Introduction

This chapter serves as the scientific foundation for the review of the secondary (welfare-based) National Ambient Air Quality Standards (NAAQS) for PM. The Clean Air Act definition of welfare effects includes, but is not limited to, effects on soils, water, wildlife, vegetation, visibility, weather, and climate, as well as effects on man-made materials, economic values, and personal comfort and well-being (CAA, 2005). In this review of the PM secondary NAAQS, welfare effects to be considered include PM-related visibility (Section 13.2), climate effects (Section 13.3) and materials damage and soiling (Section 13.4). As noted in the Preface, in the case of materials effects, the impacts of gaseous and particulate N and S wet deposition cannot be clearly distinguished, so both are considered in this review. The ecological effects associated with the deposition of oxides of nitrogen, oxides of sulfur and PM are being addressed in a separate review [i.e., the Integrated Science Assessment (ISA) for Oxides of Nitrogen, Oxides of Sulfur, and Particulate Matter-Ecological Criteria-(U.S. EPA, 2018)]. These PM-related ecological effects include nutrient enrichment, acidification, and sulfur enrichment associated with particle deposition, and the direct and indirect effects of PM on vegetation, soils, and biota.

The 2009 Integrated Science Assessment for Particulate Matter (2009 PM ISA) concluded that a causal relationship exists between PM and visibility impairment. Recent research provides additional evidence evaluated in the 2009 PM ISA, and confirms that a causal relationship exists between PM and visibility impairment. New research provides a better understanding of the relationship between PM composition and atmospheric visibility during a period of changing PM composition due to reduced

emissions of PM precursors. New research also indicates long-term visibility improvements throughout the U.S. There continues to be considerable uncertainty around quantifying acceptable visibility. Overall, the evidence is sufficient to conclude that a causal relationship exists between PM and visibility impairment.

The 2009 ISA concluded that a causal relationship exists between PM and climate effects—specifically on the radiative forcing of the climate system, including both direct effects of PM on radiative forcing and indirect effects involving cloud processes. Recent research reinforces and strengthens the evidence evaluated in the 2009 PM ISA, and reaffirms that a causal relationship exists between PM and climate effects. This causality determination provides greater specificity about the details of these radiative forcing effects and increased understanding of additional climate impacts driven by PM radiative effects. The IPCC AR states that "Climate-relevant aerosol processes are better understood, and climate-relevant aerosol properties better observed, than at the time of AR4 [released in 2007]" (Boucher, 2013). Research since the 2009 PM ISA has also improved characterization of the key sources of uncertainty in estimating PM climate effects, particularly with respect to PM-cloud interactions. Substantial uncertainties, however, still remain with respect to key processes linking PM and climate, both because of the small scale of PM-relevant cloud microphysical processes compared to the resolution of state-of-the-art models, and because of the complex cascade of indirect impacts and feedbacks in the climate system that result from a given initial radiative perturbation caused by PM. These uncertainties continue to limit the precision with which these effects can be quantified. Despite these remaining uncertainties, though, overall the evidence is sufficient to conclude that a causal relationship exists between PM and climate effects.

The 2009 PM ISA (U.S. EPA, 2009) concluded a causal relationship between PM and effects on materials. For most topics related to materials damage, the fundamental understanding of mechanisms of soiling and corrosion has not changed; rather, additional studies lend further support to the findings from the previous ISA and effects on some materials have been further characterized. There is new information for glass and metals including modeling of glass soiling and identifying which pollutants are most influential in metal corrosion in a multipollutant environment, and how that varies between metals. Development of quantitative dose-response relationships and damage functions for materials besides stone has also progressed, with new dose-response curves published for glass, and a new summary of available materials damage functions. Since the 2009 ISA there is a growing body of research, including quantitative assessment, of PM impacts on the energy yield from photovoltaic systems.

13.2 Effects on Visibility

13.2.1 Introduction

The 2009 PM ISA concluded that "a causal relationship exists between PM and visibility impairment" based on strong and consistent evidence that PM is the overwhelming source of visibility impairment in both urban and remote areas (U.S. EPA, 2009). Visibility refers to the visual quality of the view, or scene, with respect to color rendition and contrast definition. It is the ability to perceive landscape form, colors, and textures. Visibility involves optical and physical processes of light interacting with scenic elements and the atmosphere, as well as psychophysical processes involving human perception, judgment, and interpretation. On very clear days, near objects have bright, crisp colors and textures while objects over 200 km away may still be visible. Even when there are no distant objects, a clear day produces vibrant blue skies and bright white clouds with sharp edges. Removal and addition of visible light to an observer's sight path reduces both the contrast of near objects and the ability to see distant objects. Light between the observer and the object can be scattered into or out of the sight path and absorbed by PM or gases in the sight path. The sum of scattering and absorption of visible light due to PM and gases is referred to as light extinction, b_{ext}.

In polluted environments, light extinction by gases is usually small compared to PM (Malm, 2016; U.S. EPA, 2009). Light absorbing carbon (e.g., soot and smoke), incorporating and often referred to as elemental, black, and brown carbon (Andreae and Gelencsér, 2006), and some crustal minerals (Moosmueller et al., 2012) are the only commonly occurring PM components that absorb light. However, all particles scatter light, and scattering by particles is usually greater than absorption by particles or than scattering or absorption by gases (Hand et al., 2011). Particulate scattering is dependent on particle shape, refractive index, and size. Provided these properties are known, light scattering can be accurately calculated for a distribution of particles.

The linkage between PM and human perception of haze[84] involves a number of physical/chemical/optical and psychophysical processes. These processes can be divided into three broad categories, around which the discussion of the evidence is largely organized: 1) the impairment of visibility by haze; 2) the spatial, temporal, and compositional distributions of PM and their optical properties causing the haze; and 3) human perception of and response to the haze.

Evidence in the 2009 PM ISA (U.S. EPA, 2009) supported that PM was the overwhelming source of visibility impairment in both urban and remote areas, and light scattering by gases contributed

[84]In Sections 13.2 and 13.3, the term haze is used as a qualitative description of the blockage of sunlight by dust, smoke, and pollution. This usage is widespread in the scientific literature on visibility and in discussion of the Regional Haze Rule (U.S. EPA, 2003). This contrasts with the use of the term haze in Section 13.4, where it is used as defined in the scientific literature on soiling of glass, i.e., the ratio of diffuse transmitted light to direct transmitted light (Lombardo et al., 2010).

substantially only under pristine conditions. Elemental carbon (EC) and some crustal minerals are the only common PM components that absorb light, and that light scattering is greatest for particles in the size range from 0.3 to 1.0 μm (U.S. EPA, 2009). The 2009 PM ISA (U.S. EPA, 2009) also described methods for estimating contributions of PM components to light extinction as well as direct optical measurements for light scattering, absorption, and total extinction (U.S. EPA, 2009). Particulate sulfate was found to be the dominant source (>40% of PM light extinction) of regional haze in the Eastern U.S. and an important contributor (>20% of PM extinction) elsewhere in the U.S. EC and organic carbon (OC) were found to be responsible for 10−40% the haze in the U.S., with the greatest contribution in the Northwest, although per unit mass sulfate had a greater impact on visibility because of its hygroscopicity. Particulate nitrate was found to be a substantial contributor in the Midwest and California and crustal material was an important contributor in the Southwest (U.S. EPA, 2009). Human perception of visibility impairment was also reviewed in the 2009 PM ISA (U.S. EPA, 2009) based on estimates of median acceptable values from existing visibility preference studies.

The discussion of PM visibility impairment opens with reviews of metrics and monitoring methods and approaches used for evaluating visual air quality and advances in their development (Section 13.2.2). The relationship between PM and visibility impairment, including the central role of mass scattering efficiencies and advances in their use to estimate atmospheric light extinction from network PM data are then described (Section 13.2.3). Next, recent PM network data are examined to provide an up to date summary of spatial and temporal visibility patterns (Section 13.2.4). Finally, reviews of new approaches to evaluating human perception and preferences concerning atmospheric visibility and its value are provided (Section 13.2.5).

13.2.2 Visibility Impairment

13.2.2.1 Visibility Metrics

Two fundamental characteristics of atmospheric visibility impairment are 1) a reduction in *visual range*, the greatest distance through the atmosphere at which a prominent object can be identified, and 2) a reduction in *contrast*, the sharpness with which an object can be distinguished from another object or background (Malm, 2016). Both of these concepts can be understood in terms of an *atmospheric extinction coefficient* that relates the distance of an observed object to atmospheric light extinction following the Beer-Lambert Law (Finlayson-Pitts and Pitts, 2000).

The atmospheric extinction coefficient (b_{ext}) is a measure of the alteration of radiant energy as it passes through the atmosphere. b_{ext} can be expressed as the sum of light scattering by particles (b_{sp}), scattering by gases, known as Rayleigh scattering (b_{sg}), absorption by particles (b_{ap}), and absorption by gases (b_{ag}):

$$b_{ext} = b_{sp} + b_{sg} + b_{ap} + b_{ag}$$

Equation 13-1

b_{ext} varies with concentration and composition of scattering and absorbing substances in the atmosphere, and is especially useful for relating visual properties of distant objects theoretically to known concentrations and characteristics of atmospheric species (Malm, 2016). According to Malm (2016). Consequently, as described in Section 13.2.1, light extinction by gases is usually small compared to PM, and b_{sp} and b_{ap} are the main contributors to b_{ext}.

Contrast and visual range can both be conceptualized in terms of b_{ext}. The contrast can be between a haze layer and its background or between two different elements within a landscape feature, referred to as contiguous contrast. Contrast can be expressed in terms of a single color or as a color contrast. *Threshold contrast* is the reduction of contrast between two features to a point where it can just be seen (Malm, 2016). A *suprathreshold* value is a contrast change that is just noticeable when a landscape feature is clearly visible (Malm, 2016). If the background is the sky and light is uniform then contrast follows the Koschmieder relationship $C_r = C_o T_r$, (Middleton, 1968; Koschmieder, 1924), where T_r is the transmittance over path length r (Malm, 2016). The uniform sky light conditions necessary for the Koschmieder relationship to be valid do not always hold, but are most likely to be met under hazy conditions (Malm, 2016). If uniform light conditions are met, the Koschmieder relationship works well for perceptibility of isolated scenic elements, but uncertainty increases as light conditions become less uniform. Also, contrast is a scene-dependent metric based on the perception of a single object, and may not be representative of responses to visual characteristics of the scenic view as a whole (Malm, 2016). This limits its use for comparing visual impairment between different scenes or locations. Still, the Koschmieder relationship is widely used for assessing atmospheric visibility impairment, including the explanation of visual range.

If a just visible black object is viewed against the sky and the sky radiances at the observer and landscape feature are equal, then the Koschmeider relationship can be used to define the visual range as

$$V_r = \frac{-ln(\varepsilon)}{\bar{b}_{ext}}$$

Equation 13-2

where ε is the threshold contrast (a contrast level that can just be detected). If $\bar{b}_{ext} = b_{ext}$ and the threshold contrast ε is taken to be 0.02 based on historical observations (Malm, 2016), visual range can be calculated from b_{ext}:

$$V_r = \frac{3.912}{b_{ext}}$$

Equation 13-3

If b_{ext} is constructed such that Rayleigh scattering, i.e., b_{sg}, is set equal to 10 Mm^{-1}, then V_r is known as the standard visual range (SVR), which by Equation 13-3 is 391 km.

Visual range and extinction coefficient are metrics that can be consistently measured and used to assess visual air quality and track its changes and responses to emissions and PM. A third widely used metric the deciview haze index is a log transformation of light extinction (Pitchford and Malm, 1994):

$$dv = 10\left(ln\frac{b_{ext}}{0.01\ km^{-1}}\right)$$

Equation 13-4

The deciview is similar to the decibel for acoustic measurements. A one deciview (dv) change is about a 10% change in light extinction, which is a small change that is detectable for sensitive viewing situations. The haze index in deciview units is an appropriate metric for expressing the extent of haze changes where the perceptibility of the change is an issue. The Regional Haze Rule has adopted the deciview haze index as the metric for tracking long-term haze trends of visibility-protected federal lands (U.S. EPA, 2001).

Due to the dependence of the perception of haze by the human observer, scenic elements, and atmospheric optics, a number of different visibility metrics have been proposed over the years. They tend to fall into two broad categories: those metrics that are scene dependent, incorporating landscape characteristics and possibly human responses to the changes and those metrics that are independent of the scene but depend only on optical characteristics of the atmosphere, also called universal metrics.

Atmospheric extinction coefficient, visual range, and deciview are all universal, or scene independent metrics. There are also scene-dependent metrics, which incorporate changes in the radiance from landscape features and possibly human responses due to haze and depend on the landscape features, haze, illumination, and possibly the observer. Although these metrics are dependent on multiple scene features, it is also useful to have metrics that can directly relate human judgments of the visual air quality of a scene under varying haze conditions to a basic atmospheric variable such as light extinction. Contrast is a scene dependent metric. Numerous other universal and scene dependent metrics have been developed, but are not included in this assessment because they have not been used in studies reviewed here and were thoroughly reviewed recently (Malm, 2016).

13.2.2.2 Monitoring of Visibility Impairment

Direct PM light extinction, scattering, and absorption measurements are considered more accurate estimates derived from PM mass measurements because they do not depend on assumptions about particle characteristics (e.g., size, shape, density, component mixture, etc.). They can also be made with high time resolution, allowing characterization of subdaily temporal patterns of visibility impairment. Methods for measurement of light extinction, scattering, and absorption were reviewed in the 2009 PM ISA, which

included discussion of transmissometers for measurement of path-averaged light extinction and integrating nephelometers for measurement of light scattering. The use of integrating nephelometers for investigating effects of ambient PM size and water growth characteristics on light scattering was also described. The discussion also included measurement of PM light absorption by transmittance through filters on which PM has been collected as well as with aethelometers and photoacoustic instruments (U.S. EPA, 2009). Not reviewed in the 2009 PM ISA were methods for measuring scene-dependent visibility metrics that quantify the appearance of the view, accounting for the effects of particle and lighting conditions on the appearance of the scene. These include teleradiometers and telephotometers as well as photography and photographic modeling, which were described in the 2004 PM AQCD (U.S. EPA, 2004) and recently updated by Malm (2016). The discussion here is focused on strengths, limitations, and new developments of methods that were also discussed in the 2009 PM ISA (U.S. EPA, 2009), but includes recent research results that confirm or add to this body of knowledge. The convention for visibility monitoring is to make measurements at or near 550 nm, which is the wavelength of maximum eye response.

The integrating nephelometer was described in the 2009 PM ISA (U.S. EPA, 2009). It is characterized by high sensitivity and good sample control options and has been a widely used scattering instrument for air-quality-related visibility and PM monitoring purposes (Charlson et al., 1974). Integrating nephelometers significantly underestimate large particle scattering (Mueller et al., 2011b; Massoli et al., 2009; Mueller et al., 2009; Quirantes et al., 2008; Anderson and Ogren, 1998). Thus, they are better suited to measure scattering from fine PM than total or coarse PM. Historically, nephelometer chambers have been heated by radiation from their lamps and nearby electronics, drying out hygroscopic particles such as sulfates and nitrates underestimating ambient scattering. Current nephelometers generally use LED light sources, substantially reducing heating and its effects (Mueller et al., 2011b). Polar nephelometers measure the scattering as a function of scattering angle and thus can define the scattering phase function for a given aerosol (Dolgos and Martins, 2014; McCrowey et al., 2013). This can be important for visibility impairment assessments, since the path function will vary as a function of sun, landscape features, and observer geometry.

Forward and backscatter monitors measure light scattering in a prespecified solid angle (Heintzenberg, 1978). Open-air, forward scattering instruments are robust instruments and are extensively used by the National Weather Service (NWS) Automated Surface Observing System (ASOS) for characterizing visibility, principally for transportation safety purposes (NOAA, 1998; Richards et al., 1996). These instruments are also increasingly being used in Asian air quality and visibility studies, e.g., Shahzad et al. (2013) and Wang et al. (2014b).

Light absorption by PM is typically due mostly to black carbon (BC), with some contribution from organic matter also possible (Petzold et al., 2013). Soil or dust particles in the atmosphere also contribute to potentially significant amounts of atmospheric absorption (Fialho et al., 2014). Aerosol absorption measurements are made from a loaded filter based on the reflectance and transmittance of light

through the filter (Moosmüller et al., 2009; Bond et al., 1999) or in situ using a variety of methods including photoacoustic absorption spectrometry (Moosmüller et al., 2009).

All filter-based measurements require adjustments to the optical measurements to account for filter and sampled particle light-scattering effects associated with particles concentrated on and within the matrix of the filters (U.S. EPA, 2009; Bond et al., 1999). In a recent intercomparison of filter based absorption measurements, Mueller et al. (2011a) found a large variation in response from the different instruments and concluded that current correction functions for these measurements are not adequate. Quartz or glass fiber filters are the most widely used substrates in filter based absorption measurements. Organic gases are known to adsorb onto these filter media biasing organic carbon measurements, and these can be pyrolyzed to form artifact BC during the analysis, producing substantial biases in filter-based absorption measurement (Vecchi et al., 2014).

In situ measured absorption was also described in the 2009 PM ISA (U.S. EPA, 2009), and does not suffer from filter-based artifacts. Two first principle methods are absorption measured by extinction-minus-scattering and photoacoustic absorption spectrometry. The extinction-minus-scattering method suffers from potentially large subtraction errors for aerosols with high single scattering albedo and systematic errors such as the truncation errors in nephelometer scattering measurement for large particles (Singh et al., 2014; Moosmüller et al., 2009). Photoacoustic spectrometry operates by measuring the changes in pressure waves resulting from the heating and cooling of absorbing aerosols from a pulsed source of electromagnetic energy, typically a laser (Arnott et al., 2005; Arnott et al., 1999). These methods have been found to have low errors (Moosmüller et al., 2009). New developments include the combination of photoacoustic absorption measurements with integrating nephelometer in the same instrument package. For example, Sharma et al. (2013) developed a new multiwavelength, photoacoustic nephelometer spectrometer that measures scattering and absorption at wavelengths of 417, 475, 542, 607, and 675 nm.

Transmissometers measure the change in light intensity over a known distance from which b_{ext} can be derived. Long-path transmissometers were with path lengths up to 10 km were described in the 2009 PM ISA, and were concluded to suffer from a number of interferences that can cause large errors and difficulty in data interpretation (U.S. EPA, 2009; Debell et al., 2006). Cavity ring-down transmissometers do not suffer from these interferences. In this configuration, a beam of light, typically with wavelengths between 500 and 600 nm, is reflected back and forth between mirrors through an air sample, and the decay in the beam intensity over time is measured (Singh et al., 2014; Fiddler et al., 2009; Moosmuller et al., 2005; Wheeler et al., 1998). A disadvantage of the cavity ring-down configuration is that it is a point measurement and does not account for changes in b_{ext} over a sight path.

For scene-dependent visibility metrics, digital cameras have become used in much the same way as teleradiometers, recording signals proportional to radiance from all landscape features in the view. Digital or photographic cameras can be used to collect two-dimensional arrays, referred to as pixels, of film densities or digitized voltages in three color channels that are proportional to the image radiance

field, and if calibrated properly, provide quantitative radiance levels over the scene (Malm, 2016; Du et al., 2013). Advances have also been made in the application of photography in a less polluted environment. Most studies of visibility impairment have been carried out under fairly hazy conditions in urban environments, where fairly uniform lighting conditions correspond closely to conditions of the Koschmieder relationship. Furthermore, urban scenes tend to be gray, devoid of color associated with vegetation or brightly colored cliffs or terrain faces, such as those viewed in many of our national parks and wilderness areas. Bright edges of cloud formations are typically far enough from the observer to be obscured by heavy haze levels. Malm et al. (2015) investigated the ability to extract useful visibility metrics from routine webcams located in low-haze environments, specifically at the Grand Canyon National Park, Arizona, and Great Smoky Mountains National Park, Tennessee. This task is made more challenging by the effects of greater changes in lighting conditions that occur in low-haze conditions. Nonetheless, it was shown that meaningful relationships between metrics derived from the webcam images and atmospheric optical variables could be obtained as long as the indices were averaged over sufficient time to average out the effects of changing lighting.

13.2.3 Relationship between Particulate Matter and Visibility Impairment

Our understanding of the relationship between light extinction and PM mass has changed little since the 2009 PM ISA (U.S. EPA, 2009). Briefly, the impact of PM on light scattering depends on particle size and composition as well as relative humidity. All particles scatter light as described by Mie theory, which relates light scattering to particle size, shape, and index of refraction (Van de Hulst, 1981; Mie, 1908). Hygroscopic particles like ammonium sulfate, ammonium nitrate, and sea salt exhibit substantial growth as relative humidity increases, leading to increased light scattering (U.S. EPA, 2009). For externally mixed particles, a linear relationship between the b_{ext} is the sum of the mass concentration of each PM species multiplied by its specific mass extinction efficiency can be derived from Mie theory (Ouimette and Flagan, 1982):

$$b_{ext} = \sum_{j} a_j \, f_j(RH) M_j$$

Equation 13-5

where the species (j) mass concentration is given by M_j ($\mu g/m^3$); its extinction efficiency is given by α_j ($m^2 g^{-1}$); and its hygroscopic scattering growth factor given by $f_j(RH)$. The particle species j can be for a single compound or class of compound, such as particulate organic matter or even $PM_{2.5}$.

Equation 13-5 not only describes the theoretical relationship between light extinction and PM characteristics, but also provides the basis for practical use of mass scattering efficiencies in combination with ambient PM concentration data to estimate light extinction. This approach was previously described in the 2009 PM ISA (U.S. EPA, 2009), but is included here because it was used to estimate the extinction data used to examine seasonal and spatial patterns of visibility impairment in Section 13.2.4.

Equation 13-5 strictly applies to external mixtures of PM, i.e., PM is composed of a mixture of species, but each single particle is composed of only one of species. Although ambient PM is usually a complex and unknown combination of both internal and external mixtures of PM components, differences in calculated light extinction using various external and internal mixture assumptions were generally less than about 10%. As a result, the form of Equation 13-5 has been accepted as a reasonable approach to apportioning light extinction to PM components (U.S. EPA, 2009).

Applying Equation 13-5 to major PM species generates Equation 13-6, which was developed specifically for use with PM monitoring data (Section 13.2.4) (U.S. EPA, 2009; Malm et al., 1994):

$$b_{ext} \cong 3f(RH)([AS] + [AN]) + 4[OM] + 10[EC] + 1[FS] + 0.6[CM] + 10$$

Equation 13-6

Light extinction (b_{ext}) is in units of Mm^{-1}; [AS], [AN], [OM], [EC], [FS], [CM] are the concentrations in $\mu g/m^3$ of ammonium sulfate, ammonium nitrate, organic matter, elemental carbon, fine soil, and coarse mass, respectively; f(RH) is the relative-humidity-dependent water growth function, and the various coefficients are empirically derived mass scattering and absorption coefficients originally proposed by (Malm et al., 1994). Particulate organic matter concentration [OM] is derived from measured organic carbon concentration [OC] by multiplying by a factor of 1.4, [OM] = 1.4 [OC]. Equation 13-6 is widely referred to as the *original IMPROVE algorithm* to distinguish it from subsequent variations developed later. Although considerable research has focused on evaluating mass extinction coefficients, assessing the linearity of the relationship, and investigating the need for additional terms, a modification of Equation 13-6 (Hand et al., 2011) remains widely used for relating light extinction to PM components, including this document. Three major modifications were made to the Equation 13-6 for use in the most recent IMPROVE network report (Hand et al., 2011):

- A sea salt term was added.
- The factor used to compute particulate organic matter concentration from organic carbon concentration was increased from [OM] = 1.4[OC] to [OM] = 1.8[OC].
- A site-specific term based on elevation and mean temperature was used for Rayleigh scattering (gas scattering) instead of the constant value of 10 Mm^{-1} used in the original equation for all sites.

The resulting equation has been referred to as the *modified original IMPROVE algorithm* to distinguish it other, more extensive revisions:

$$b_{ext} \cong 3f(RH)([AS] + [AN]) + 4[OM] + 10[EC] + 1[FS] + 1.7f(RH)[SS]$$

Equation 13-7

where [SS] is sea salt concentration. All estimates of light extinction from $PM_{2.5}$ species in this document were made with Equation 13-7.

13.2.3.1 Estimated Mass Extinction

Mass scattering efficiencies, α_{sp}, can be calculated for single particle components or composites of different particle types, e.g., $PM_{2.5}$. The three main methods for calculating mass scattering efficiencies, α_{sp}, are 1) as a simple ratio of measured mass concentrations to measured light scattering coefficients, 2) by multilinear regression with b_{ext} as the independent variable and the measured PM mass concentrations for each species as the dependent variables, and 3) from Mie theory (see Section 13.2.3.1) if PM distribution, chemical composition, and optical properties are known (Malm, 2016; U.S. EPA, 2009; Hand and Malm, 2007). Average dry mass scattering efficiencies estimated by various methods from ground-based measurements in a survey of 60 studies since 1990 by Hand and Malm (2007). Results were briefly discussed in the 2009 PM ISA (U.S. EPA, 2009) and are more fully presented in Table 13-1. The results for individual species were considered generally consistent with the coefficients of Equation 13-6 or Equation 13-7 (U.S. EPA, 2009).

Table 13-1 Mass scattering efficiencies for urban, remote, and ocean regions.

Species/Mode[a]	Urban (m^2/g)	Remote/Rural Continental (m^2/g)	Ocean/Marine (m^2/g)	All Methods (m^2/g)
Fine mixed	3.2 ± 1.3 (32)	3.1 ± 1.4 (24)	4.1 ± 0.8 (42)	3.6 ± 1.2 (98)
Coarse mixed	0.6 ± 0.3 (6)	0.7 ± 0.4 (24)	1.6 ± 1.0 (21)	1.0 ± 0.9 (51)
Total mixed	1.7 ± 1.0 (14)		2.5 ± 1.0 (6)	1.9 ± 1.1 (20)
Fine sulfate	2.6 ± 0.7 (9)	2.7 ± 0.5 (56)	2.0 ± 0.7 (28)	2.5 ± 0.6 (93)
Fine nitrate	2.2 ± 0.5 (6)	2.8 ± 0.5 (42)		2.7 ± 0.5 (48)
Fine POM	2.5 (1)	3.1 ± 0.8 (38)	5.6 ± 1.5 (19)	3.9 ± 1.5 (58)
Coarse POM			2.6 ± 1.1 (19)	2.6 ± 1.1 (19)
Total POM			3.5 ± 0.9 (8)	3.5 ± 1.0 (8)
Fine dust		2.6 ± 0.4 (4)	3.4 ± 0.5 (19)	3.3 ± 0.6 (23)
Coarse dust		0.5 ± 0.2 (3)	0.7 ± 0.2 (19)	0.7 ± 0.2 (22)
Total dust		0.71 (1)	1.1 ± 0.4 (11)	1.1 ± 0.4 (12)
Fine sea salt		1.8 (1)	4.6 ± 0.7 (24)	4.5 ± 0.9 (25)
Coarse sea salt			0.96 ± 0.18 (21)	1.0 ± 0.2 (21)
Total sea salt			2.1 ± 0.5 (10)	2.1 ± 0.5 (10)

[a]Mode is listed in the table as fine or coarse rather than $PM_{2.5}$ and $PM_{10-2.5}$ because the variety of sampling and estimation methods used may not have always been based on $PM_{2.5}$ or $PM_{10-2.5}$ sampling methods.

Source: Permission pending, Malm and Hand (2007).

There is a broad range in scattering efficiencies across both regions and species in Table 13-1. Part of this variability is due to the different methods and their varying biases and uncertainties used in each study. Therefore, the true variances in mass scattering efficiencies due to microphysical differences in the particles are likely smaller. Based on their review, Hand and Malm (2007) made a series of recommendations for the dry mass scattering efficiencies for the visible wavelengths listed in Table 13-2.

Table 13-2 Mass scattering efficiency recommendations.

Species	Recommendation (m^2/g)	Comment
$PM_{2.5}$ ammonium sulfate	2.5	2 m^2/g in dry, clean environments 3 m^2/g in more polluted environments
$PM_{2.5}$ ammonium nitrate	2.7	
$PM_{2.5}$ organic matter	3.9	assuming carbon multiplier of 1.8
$PM_{2.5}$ soil	3.3	assuming perfect 2.5 μm cut point ~1 m^2/g for IMPROVE, CSN samplers
$PM_{2.5}$ sea salt	4.5	assuming perfect 2.5 μm cut point 1−1.3 m^2/g for more realistic samplers
Mixed $PM_{10-2.5}$ mass	1	large variability depending on RH, PM composition, PM size distribution
Mixed $PM_{2.5}$ mass	3.6	large variability depending on RH, PM composition, PM size distribution

Source: Permission pending, Hand and Malm (2007).

Mass scattering efficiencies from a number of studies in urban and rural environments were reported since the publication of these recommendations (Cheng et al., 2015; Pandolfi et al., 2014; Tao et al., 2014; Titos et al., 2012; Wang et al., 2012; Malm et al., 2009; Wagner et al., 2009; Andreae et al., 2008; Cheng et al., 2008). Overall, within a given species or mix of PM, there is wide variation in results, with over a factor of 2 or more difference between average results across the studies. However, these values are within the range of the study results reviewed by Hand and Malm (2007). In addition, Malm et al. (2011) showed that the organic mass scattering efficiency in Equation 13-7 is also sensitive to changes in the organic composition.

In addition to mass scattering efficiencies required for all major PM species, a full accounting for light extinction also requires mass absorption efficiencies for species that absorb light. Light absorption by PM is due mostly to black carbon (BC), although some contribution from organic matter is also possible (Petzold et al., 2013). Soil or dust particles in the atmosphere also contribute to potentially substantial amounts of atmospheric absorption (Fialho et al., 2014; Moosmueller et al., 2012). While light absorption by elemental carbon is included as a term in Equation 13-7, several estimates of mass absorption efficiencies for light absorbing carbon (LAC) were published before publication of the 2009 PM ISA, but were not included in the document. To fill this gap, those earlier studies are included for the first time in this ISA along with more recent observations.

Bond and Bergstrom (2006), attempted to understand and reconcile the wide range of reported LAC absorption efficiencies and recommended a mass absorption efficiency of 7.5 ± 1.2 m^2/g for LAC. This recommendation is consistent with results of Andreae et al. (2008), who estimated the LAC absorption efficiency to be 8.5 m^2/g. When organics and LAC were incorporated into a multilinear regression analysis, the LAC absorption efficiency reduced to 7.7 m^2/g. In Fresno, California, Chow et al. (2009) derived a LAC absorption efficiency of 7.9 ± 1.5 m^2/g. The large range of values for light absorbing carbon (LAC) mass absorption efficiencies is due in large part to LAC mass concentration measurements being method dependent, as well as to dependence of the absorption efficiency on wavelength and size distribution.

Absorption is often assumed to be due to particulate black carbon that absorbs in all visible wavelengths. However, there is increasing evidence that organic carbon compounds such as organonitrates absorb light in the near-ultraviolet–blue wavelengths (Lack et al., 2013; Claeys et al., 2012; Kitanovski et al., 2012). This absorption can be significant, with organic mass absorption efficiencies at ~400 nm in a smoke plume varying between 0.25 m^2/g and 2.9 m^2/g (Lack et al., 2013; Yang et al., 2009; Hoffer et al., 2006; Kirchstetter et al., 2004)). It is also missed by measurement methods that focus on green wavelengths, i.e., $\lambda \sim 550$ nm. The absorption of brown carbon in the blue wavelengths is important from a radiation balance standpoint. However, since brown carbon has little absorption in the green and red wavelengths, this should have only a small effect on visibility.

13.2.3.2 Hygroscopic Growth

The relative humidity growth functions in Equation 13-7 are the same for both sulfate and nitrate and are based on experimental growth curves for ammonium sulfate in their most hydrated state (Pitchford et al., 2007; Malm et al., 1994). The growth curves used are supported by a number of recent field studies (Lowenthal et al. (2015); (Chen et al., 2014; Liu et al., 2013; Liu et al., 2012; Stock et al., 2011; Achtert et al., 2009).Numerous laboratory studies have also shown that organic coatings on inorganic particles induce a lower deliquescence point compared to that of the pure inorganic compounds (Li et al., 2014; Peckhaus et al., 2012; Smith et al., 2012; Wu et al., 2011; Pope et al., 2010), and mixed-salt particles generally deliquesce at lower relative humidity than the single-salt particles (Freney et al., 2009). Consequently, outside of very dry environments, even ambient, fully neutralized inorganic salts would generally exhibit smooth growth with relative humidity.

Water uptake by particulate organic matter is not well understood, and in Equation 13-7 the size of organic particles is assumed to be independent of relative humidity, based on the observed the relationship between relative humidity and PM mass with high organic content (Reid et al., 2005; Malm et al., 2003). More recent studies suggest that organic mass is at least slightly hygroscopic, with observations of wet particle diameter/dry particle diameter of water soluble organic PM and humic-like substances from urban, rural, and biomass burning samples ranging from 1.08 to 1.10 at RH of 80%

(Lowenthal et al., 2015; Hallar et al., 2013), 1.13 to 1.19 at RH of 90% (Lowenthal et al., 2015; Kristensen et al., 2012), and 1.25 at RH of 95% (Kristensen et al., 2012) Organics are a significant contributor to urban $PM_{2.5}$ (see Chapter 2) and the exclusion of an f(RH) term for organics in Equation 13-6 likely results in an underestimation of the urban reconstructed b_{ext}.

13.2.3.3 Reconstructing b_{ext} from PM Speciation Data

In addition to the slight modification to develop Equation 13-7 from Equation 13-6, other revisions or rearrangements have been developed as attempts to improve performance or convenience, and results to these changes have been evaluated recently. Equation 13-6 tended to underestimate the highest light scattering values and overestimate the lowest values at IMPROVE monitors throughout the U.S. (Malm and Hand, 2007; Ryan et al., 2005; Lowenthal and Kumar, 2004), in the polluted Pearl River Delta region, and in Shanghai, China using 24-hour $PM_{2.5}$ filter samples (Deng et al., 2013) or $PM_{2.5}$ speciation data from semicontinuous monitors with higher time resolution (Cheng et al., 2015; Zhang et al., 2013b). Limited field studies suggested that particle size distributions and associated mass scattering coefficients may increase with concentrations (Lowenthal and Kumar, 2004; Malm et al., 2003). Although little research has been carried out on urban areas in the U.S., a similar shift of particle size distribution to larger sizes with increasing concentrations in rural and urban settings has been consistently observed in more recent studies in Europe and China (Cheng et al., 2015; Tian et al., 2014; Wang et al., 2014a; Wang et al., 2012; Yang et al., 2012; Calvo et al., 2010; Yue et al., 2009; Baeumer et al., 2008).

To resolve these biases, *a revised IMPROVE equation* was developed (Pitchford et al., 2007) that divides PM components into small and large particle sizes with separate mass scattering efficiencies and hygroscopic growth functions for each size. The revised IMPROVE *equation* was described in detail in the 2009 PM ISA (U.S. EPA, 2009), and it both reduced bias at the lowest and highest scattering values and improved the accuracy of the reconstructed $b_{ext.}$ However, poorer precision was observed with the revised IMPROVE equation compared to the original IMPROVE equation, indicating that the revised equation introduced new random errors. The differences resulting from the two equations in identifying the best and worst haze conditions and the apportionment of the various PM components were small (U.S. EPA, 2009).

Lowenthal and Kumar (2016) recently tested assumptions and evaluated the performance of the revised IMPROVE equation in National Parks and suggested further modifications were needed. They observed that the ration of [OM]/[OC] was closer to 2.1 than the currently used value of 1.8. They also observed that water soluble organic matter absorbs water as a function of RH, which is not accounted for in either the original or revised IMPROVE equations. They further reported that sulfate was not always completely neutralized, as assumed by both the original and the revised IMPROVE equation. Their results suggested that light scattering by sulfate was overestimated and light scattering by organic matter was underestimated by the revised IMPROVE equation. They concluded that the revised IMPROVE equation

did not resolve the biases it was intended to address, and that it should be re-examined (Lowenthal and Kumar, 2016).

Equation 13-6 has also been rearranged for convenient use with hourly measured RH, $PM_{2.5}$, and NO_2, and historical monthly averaged particulate composition (So et al., 2015). Overall, r^2 for all study sites, including those without site-specific speciation data, ranged from 0.72 to 0.77, and absolute normalized mean bias and normalized mean error were generally less than 5% and 25%, respectively, at all sites. Although NO_2 extinction was included in the study, it was mainly used to determine how much of the total extinction was due to $PM_{2.5}$, and conclusions were limited to $PM_{2.5}$ extinction.

In Equation 13-6 and Equation 13-7 it is assumed that the particle species are externally mixed, but this is generally not the case (Degheidy et al., 2015). Although previous studies have indicated that differences among the calculated light extinction values using external and various internal mixture assumptions are generally less than about 10% (U.S. EPA, 2009), newer work suggests potential nonlinearities in the resulting refractive indices of mixed particles. Freedman et al. (2009) found that the refractive indices of internal mixtures of ammonium sulfate and succinic acid were higher than for either pure compound alone at high organic mass fractions and that for mixtures of oxalic or adipic acid with ammonium sulfate, the refractive indices of the mixtures were about the same as ammonium sulfate for all organic mass fractions. Freedman et al. (2009) also calculated that a distribution of mixed particles containing 25% ammonium sulfate and 75% succinic acid resulted in 40% more scattering than would be estimated using volume-weighted, average refractive indices.

13.2.4 Seasonal and Spatial Patterns of Visibility Impairment

In this section light extinction is apportioned to PM species using data from the from the IMPROVE and CSN monitoring networks described in Chapter 2 (Section 2.4). Concentrations for all reconstructed particulate components used for estimating b_{ext} are determined using calculations listed in Table 13-3, which are based on the analyses and procedures laid out in the IMPROVE Report V (Hand et al., 2011) and related publications (Hand et al., 2014b; Hand et al., 2014a; Hand et al., 2013; Hand et al., 2012a; Hand et al., 2012b; Hand et al., 2012c). For example, the mass of ammonium sulfate (AS) is used in Equation 13-7 along with masses of other $PM_{2.5}$ species in the first column of Table 13-3 to estimate light extinction. However, the species actually measured in the CSN and IMPROVE networks is sulfate SO_4^{2-} rather than AS, which is NH_4^+ added to SO_4^{2-} and has a greater mass. Column 2 shows that the concentration of ammonium sulfate [AS] is calculated from the concentration of sulfate [SO_4^{2-}] by multiplying [SO_4^{2-}] by 1.375, which is the ratio of the equivalent mass of [AS] to the equivalent mass of [SO_4^{2-}], i.e., adding ammonium to sulfate increases its mass by a factor of 1.375.

Table 13-3 Composite PM components.

$PM_{2.5}$ Species[a]	Calculation[b]	Assumptions
Ammonium sulfate AS = $(NH_4)_2(SO_4)$	$1.375[SO_4^{2-}]$	Sulfate is assumed to be fully neutralized for both IMPROVE and CSN data.
Ammonium nitrate AN = NH_4NO_3	$1.29[NO_3^-]$	Nitrate is assumed to be ammonium nitrate for both IMPROVE and CSN data.
Particulate organic matter (POM)	1.8[OC]	Derived from organic carbon (OC), assuming an average organic molecule is 55% carbon.
Light absorbing carbon (LAC)	LAC	
Fine particulate soil	2.2[Al] + 2.49[Si] + 1.63[Ca] + 2.42[Fe] + 1.94[Ti]	Fine soil is composed of common metal oxides; FeO and Fe_2O_3 are equally abundant; soil potassium = 0.6[Fe]; a factor of 1.16 is used to account for other compounds such as MgO, Na_2O, CO_3. Same assumption for both IMPROVE and CSN data.
Sea salt (SS)	$1.8[Cl^-]$ or 1.8[Cl]	Sea salt is 55% chloride by weight. IMPROVE sea salt is computed from chloride ion data, while CSN is computed from chlorine concentrations, since Cl^- is not available.
Dry reconstructed fine mass (RCFM)	[AS] + [AN] + [POM] + [LAC] + [Soil] + [SS]	
Coarse mass	$[PM_{10}] - [PM_{2.5}]$	

[a]Species used in Equation 13-7.

[b]The species measured in IMPROVE and CSN network is not exactly the same as the species used in Equation 13-7. The calculation column lists the factor multiplied by the measured species to give the calculated species concentration actually used in Equation 13-7. For example, sulfate is measured in the IMPROVE and CSN networks, but available mass scattering efficiencies are for ammonium sulfate. Therefore, the measured sulfate concentrations must be converted to ammonium sulfate by calculating the corresponding ammonium sulfate mass from the measured sulfate mass.

Sources: Hand et al. (2014b); Hand et al. (2014a); Hand et al. (2013); Hand et al. (2012a); Hand et al. (2012b); Hand et al. (2012c); Hand et al. (2011)

$PM_{2.5}$ mass reconstruction methods were recently reviewed, uncertainties in $PM_{2.5}$ mass concentration, and reconstructed PM components in the IMPROVE and CSN networks using multiple linear regression methods (Chow et al., 2015; Malm et al., 2011). In addition, several field studies in rural environments tested some of the assumptions in Table 13-3, concluding that ammonium sulfate was fully neutralized and particle size with increasing RH followed a smooth growth curve (Lowenthal et al., 2015; Lowenthal et al., 2009). $PM_{2.5}$ concentrations are directly measured in the IMPROVE network. Particulate sulfate is assumed to be fully neutralized ammonium sulfate and estimated from the sulfate ion

measurement. Particulate nitrate is assumed to be in the form of ammonium nitrate from the reaction of nitric acid and ammonia gas. Organic mass is estimated by scaling the OC from the thermal optical reflectance analysis to particulate organic mass (POM) where the scale factor accounts for oxygen, hydrogen, and other noncarbon molecules. It was assumed that the ratio of POM divided by OC mass (ROC) was 1.8, or 55% of POM was carbon. This value was based on a regression analysis of the major PM composite components against measured $PM_{2.5}$ concentrations in the IMPROVE network (Malm and Hand, 2007).

LAC is the EC concentration reported from the thermal optical analysis of organic carbon (OC) and elemental carbon (EC) (Watson et al., 2005). Soil mass concentrations are estimated by a general method that sums the oxides of elements that are typically associated with soil (Al_2O_3, SiO_2, CaO, K_2O, FeO, Fe_2O_3, TiO_2). To account for other compounds such as MgO, Na_2O, and carbonates, the sum is multiplied by a factor of 1.16 (Malm et al., 1994). Molar concentrations of iron are assumed to be equally abundant in the forms of FeO and Fe_2O_3, and soil potassium is estimated by using Fe as a surrogate, or [K] = 0.6[Fe], because unlike Fe and other soil elements, the K in $PM_{2.5}$ is also contributed in abundance by another source, biomass burning (Malm et al., 1994). Sea salt concentrations are typically computed from sea salt markers, with the most common being sodium (Na). The Na ion is not routinely measured in the IMPROVE program, and elemental Na is poorly detected by IMPROVE's routine X-ray fluorescence analysis (White, 2008), so the chloride ion is used instead (Table 13-3).

The chloride ion has been shown to be a good predictor of conserved sea salt mass near coastal areas (White, 2008) but can be lost during atmospheric aging due to reactions with nitric acid, which produces particulate sodium nitrate and gaseous hydrochloric acid. The use of the chloride ion likely results in an underestimation of sea salt's contribution to $PM_{2.5}$ farther away from coastal areas, but sea salt concentrations are generally reduced by dispersion and removal processes, leading to smaller contributions to $PM_{2.5}$. Elemental chlorine concentrations are used to estimate sea salt for CSN data, because the chloride ion is not analyzed by the CSN. Comparisons of sea salt concentrations between 25 collocated CSN and IMPROVE sites located throughout the U.S. observed that IMPROVE concentrations were up to three times higher on average compared to CSN, with a relative bias of 63%, or large enough for the data to be considered semiquantitative (Hand et al., 2011). Difficulties in measuring sea salt in the IMPROVE and CSN networks including the lack of Na^+ measurements as a check and depletion of Cl^- due to displacement by NO_3^- are discussed by Hand et al. (2011).

13.2.4.1 Seasonal and Spatial Light Extinction $PM_{2.5}$ Species Contributions

Approximately every five years the IMPROVE program releases a report summarizing the spatial and temporal patterns of $PM_{2.5}$ composition and its contribution to light extinction from IMPROVE and CSN monitoring sites, which are mostly urban and rural, respectively. The latest report, IMPROVE Report V, was published in 2011 (Hand et al., 2011) and included a summary of the seasonal and

geographic distributions of species contributions to $PM_{2.5}$ and light extinction for IMPROVE and CSN monitoring sites averaged over the years 2005–2008. The b_{ext} associated with $PM_{2.5}$ components was calculated using Equation 13-7 and the same monthly climatological f(RH) curves used in the Regional Haze Rule guidance document (U.S. EPA, 2003). These data can be used to identify differences between urban and rural light extinction species contributions by region and season. This contrasts with most visibility data, including data presented in the 2009 PM ISA (U.S. EPA, 2009), which have historically been based mainly on rural and remote measurements.

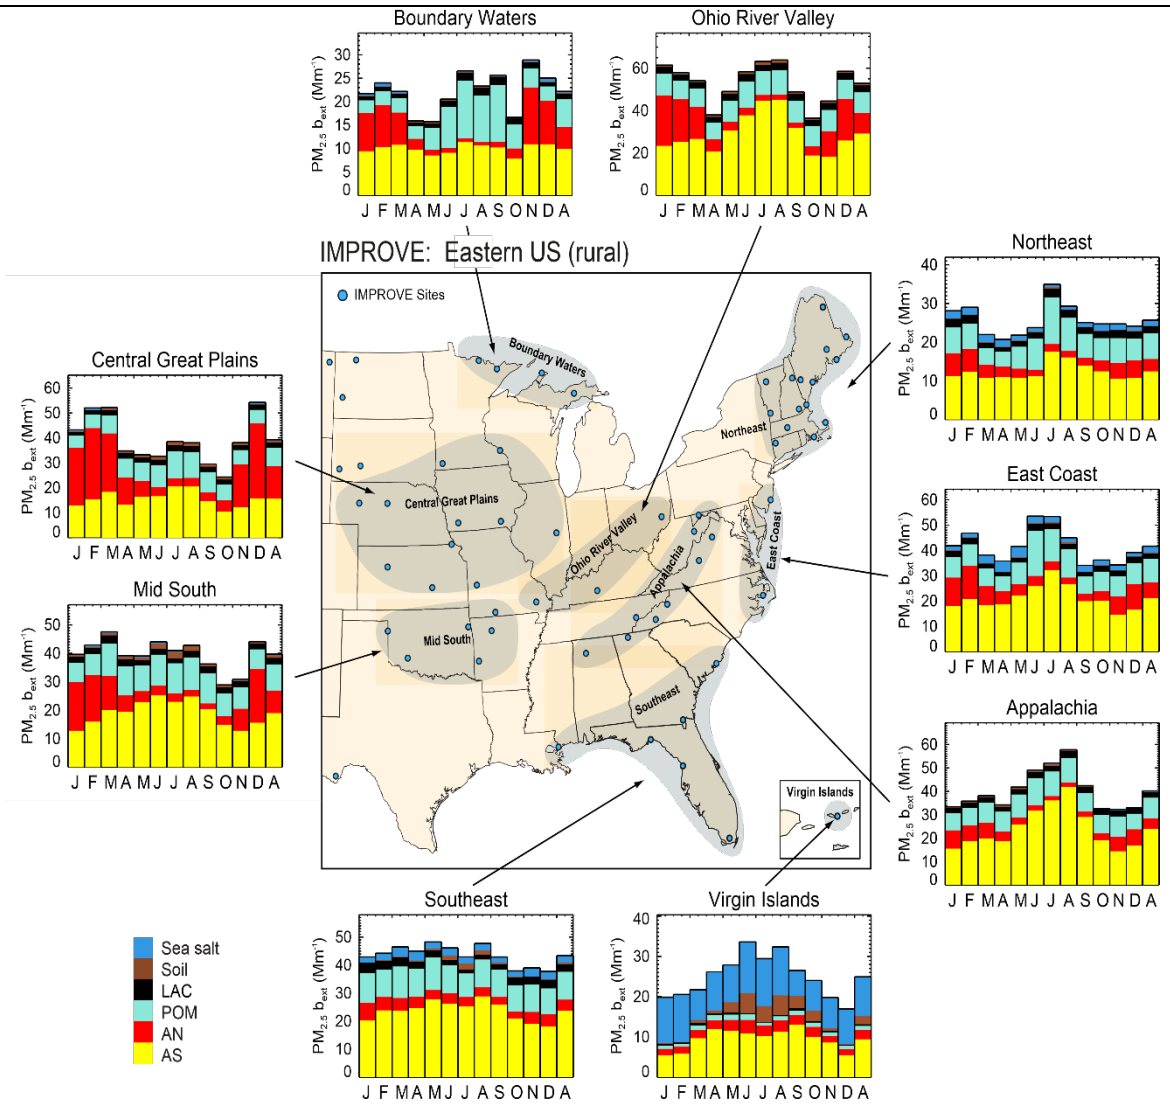
Twenty-eight IMPROVE regions were empirically defined based on-site location and magnitudes and seasonal distribution of PM concentrations for major species. Elevation was not explicitly taken into account in these groupings. Thirty-one CSN regions were defined based on seasonal distributions of PM concentrations and site locations. For comparison purposes and where possible, CSN regions were defined similarly to those for the IMPROVE network (Hand et al., 2011). Although the ability to leverage the sampling networks to provide extinction estimates provides valuable insight, these mass-based estimates are less accurate than calculations that use particle size and composition information.

Hand et al. (2012c) published the finding for the seasonal $PM_{2.5}$ species concentrations for the IMPROVE and CSN regions using PM species listed in Table 13-3, averaged over the years 2005−2008. The data were aggregated over regions or groupings of IMPROVE or CSN monitoring sites. Twenty-eight IMPROVE regions were empirically defined based on-site location and magnitudes and seasonal distribution of aerosol concentrations for major species. Elevation was not explicitly taken into account in these groupings. Thirty-one CSN regions were defined based on seasonal distributions of aerosol concentrations and site locations. Of the thirty-one CSN regions, eight had only one site per region because seasonal distributions were unique in comparison to the nearest other monitors, and these regions are identified by individual cities. Where possible, CSN regions were defined similarly to those for the IMPROVE network for comparison purposes.

Following is a summary of the $PM_{2.5}$ b_{ext} species contribution estimates from Hand et al. (2011). The b_{ext} species contributions differ from the $PM_{2.5}$ mass contributions in that the relative contribution of fine soil scattering is reduced due to its comparatively low scattering efficiency, and the relative contributions of ammonium sulfate and nitrate are increased due to the f(RH) factors. The results are presented as monthly stacked bar charts for each region in Figure 13-1, Figure 13-2, Figure 13-3, Figure 13-4, Figure 13-5, Figure 13-6, Figure 13-7, Figure 13-8, Figure 13-9, Figure 13-10, Figure 13-11, and Figure 13-12. The figures are arranged in pairs, with odd-numbered figures showing data for 2011−2014 and even-numbered figures for the same region and monitors showing data for 2005−2008. The most recent data are presented first because the discussion focuses mainly on the 2011−2014 data shown in the odd-numbered figures, but earlier data for 2005−2008 are shown for comparison. Figure 13-1, Figure 13-2, Figure 13-3, Figure 13-4, Figure 13-5, and Figure 13-6 summarize the IMPROVE b_{ext} species contributions, while Figure 13-7, Figure 13-8, Figure 13-9, Figure 13-10,

Figure 13-11, Figure 13-12, Figure 13-13, and Figure 13-14 summarize the CSN b_{ext} species contributions.

Figure 13-13 and Figure 13-14 show b_{ext} budgets for Alaska, Hawaii, and the Virgin Islands for 2005−2008 from the IMPROVE and CSN networks, respectively. These were presented separately in the original publication by Hand et al. (2011), but are included if available with other regions in the updated figures from 2011−2014 (Figure 13-3, Figure 13-5, and Figure 13-9).



Note: The letters on the x-axis correspond to the month and "A" corresponds to "annual" mean. Ammonium sulfate (AS) in yellow, ammonium nitrate (AN) in red, particulate organic matter (POM) in green, light absorbing carbon (LAC) in black, soil in brown, and sea salt in blue. The shaded area corresponds to the regions that comprise the sites used in the analysis, shown as dots. Extinction coefficients were determined from Equation 13-7 (see text). Wavelength corresponds to 550 nm.

Figure 13-14 Chemical Speciation Network 2005–2008 regional monthly mean $PM_{2.5}$ reconstructed light extinction coefficients (b_{ext}, Mm^{-1}) for Alaska and Hawaii.

Several major differences among the various regions are apparent from the 2011−2014 data. Annual average reconstructed b_{ext} is considerably higher in the East and Midwest than in the Southwest. Based on IMPROVE data, the highest annual average b_{ext} was greater than 50 Mm^{-1} in the Ohio River Valley, and annual average b_{ext} and was greater than 40 Mm^{-1} in the Southeast, East Coast, Mid-South, Central Great Plains, and Appalachian regions (Figure 13-1). In contrast, annual average b_{ext} was less than 40 Mm^{-1} for all Western IMPROVE regions (Figure 13-3 and Figure 13-5), but in the eastern half of the U.S. b_{ext} was less than 40 Mm^{-1} only for the Boundary Waters, Northeast, and Virgin Islands regions. (Figure 13-1). For perspective, a b_{ext} value of 40 Mm^{-1} corresponds to a visual range of about 100 km from Equation 13-3. Annual average b_{ext} values are also generally higher in Eastern than in Western CSN regions, although the highest annual average b_{ext} in the CSN regions are in the Sacramento/San Joaquin Valley and Los Angeles regions, and annual average b_{ext} in Alaska and other California regions are comparable to Eastern CSN regions.

Ammonium sulfate accounted for 34−60% of the annual average b_{ext}, in these Eastern regions with greatest contributions to extinction usually in the summer. Particulate organic matter (POM) was the next largest contributor, ranging from 19−32% of annual average b_{ext} with less seasonal variation. Ammonium nitrate was also important in most regions, accounting for 9−34%, with generally much higher concentrations winter than in summer (see Section 2.5).

In the Northwest (Figure 13-10 and Figure 13-13), POM was the largest contributor in most urban and rural regions, accounting for up to 69% of annual average b_{ext} and usually making its greatest contribution to b_{ext} in the fall, possibly due to wildfires. Exceptions were Boise and North Dakota, where ammonium nitrate was the greatest contributor, and the Alaska IMPROVE region, where ammonium sulfate was the greatest contributor to annual average b_{ext}.

In the Southwest IMPROVE regions (Figure 13-11), b_{ext} ammonium sulfate or POM were usually the greatest contributors to annual average b_{ext}, with close to equivalent contributions from each in several regions. In the Southwest CSN regions (Figure 13-14), ammonium nitrate was often the greatest contributor to annual average $b_{ext,}$ contributor, with especially high $b_{ext,}$ contributions in winter. Mass scattering from $PM_{10-2.5}$ was relatively small at less than 10% of the fine mass scattering in the eastern and northwestern U.S. However, in the Southwest it can be large, contributing more than 30% of the fine mass scattering in southern Arizona and New Mexico and more than 20% throughout the southwestern U.S. In the southwestern U.S., coarse mass is composed of primarily soil.

A number of differences between the urban CSN (Figure 13-12, Figure 13-13, and Figure 13-14) and mainly rural IMPROVE (Figure 13-9, Figure 13-10, and Figure 13-11) data also stand out. Light extinction is generally higher in CSN regions than geographically corresponding IMPROVE regions. Annual average total reconstructed b_{ext} exceeded 50 Mm^{-1} in 11 CSN regions, compared to only 1 IMPROVE region, and was higher than 20 Mm^{-1} in all CSN regions, but slightly more than half of IMPROVE regions. Light absorbing carbon was not among the three greatest contributors to light extinction in any IMPROVE regions, but was a substantial contributor in several Western regions,

accounting for more than 20% of annual average $PM_{2.5}$ b_{ext} in the West Texas, Albuquerque, Phoenix/Tucson, and Front Range CSN regions of the Southwest (Figure 13-11). Ammonium nitrate also accounted for more light extinction in the CSN than IMPROVE regions. It was the single greatest contributor in all of the CSN California regions as well as the Boise, Utah, North Dakota, and Chicago CSN regions. In contrast, ammonium nitrate accounted for the most extinction among all species only in the Columbia Gorge IMPROVE region.

In Equation 13-5 and Equation 13-6, b_{ext} is directly proportional mass. As a consequence, estimates of metrics like visual range, which is inversely proportional to b_{ext} (Equation 13-3), and deciview, which is a logarithmic function of b_{ext} (Equation 13-4), become less sensitive to changes in b_{ext} as PM mass increases. As a result, the same incremental increase in PM mass in a relatively clean area is predicted to have a greater impact on visual range and deciview than in a more polluted area. Because PM concentrations are generally lower in Western and rural areas than in Eastern and urban areas, these areas are likely to experience a greater incremental impact of a change in PM concentration.

Noticeable differences are also apparent when the 2011−2014 data (Figure 13-9, Figure 13-10, Figure 13-11, Figure 13-12, Figure 13-13, and Figure 13-14) are compared to data from 2005−2008 (Figure 13-1, Figure 13-2, Figure 13-3, Figure 13-4, Figure 13-5, Figure 13-6, Figure 13-7, and Figure 13-8). In 2005−2008 annual average b_{ext} exceeded 80 Mm^{-1} in most CSN regions in the Eastern U.S. (Figure 13-5), but in 2011−2014 annual average b_{ext} was less than 60 Mm^{-1} in all CSN regions (Figure 13-12). Based on Equation 13-3, this corresponds to an improvement in average visual range in most Eastern U.S. regions from less than 50 km in 2004−2008 to more than 65 km in 2011−2014. A more long-term comparison can be carried out with IMPROVE data, which extends as far back as 1988. As Figure 13-9 shows, annual average $PM_{2.5}$ b_{ext} estimates are under 50 mM^{-1} in all IMPROVE regions except the Ohio River Valley (between 55−60 mM^{-1}). This compares to estimates greater than 90 mM−1 for a wide area of the Eastern U.S. encompassing the East Coast, Appalachia, and Ohio River Valley regions of Figure 13-9 reported for 1988−1991 IMPROVE data (Malm et al., 1994).

A second major difference between the 2011−2014 data and 2005−2008 data concerns the fraction of b_{ext} accounted for by ammonium sulfate. As detailed in Section 2.5, atmospheric sulfate concentration has decreased by −2.7% per year from 1992 to 2010 and −4.6% per year from 2001−2010 at rural sites, and by −6.2% per year from 2001−2010 at urban sites due to a sharp decline in SO_2 emissions. From Equation 13-6, ammonium sulfate also makes a greater contribution to light extinction than an equivalent mass of most other species (Malm et al., 1994). The impact of decreased sulfate on visibility impairment is clearly evident at the most strongly impacted Eastern U.S. CSN regions of the Ohio River Valley, Michigan/Great Lakes, Chicago, and New York City when monthly extinction patterns are compared between 2011−2014 (Figure 13-12) and 2005−2008 (Figure 13-5). The fraction of total b_{ext} accounted for by ammonium sulfate is less in 2011−2014 than in 2005−2008, and monthly ammonium sulfate b_{ext} show less difference between summer months and monthly b_{ext} estimates from other times of year.

13.2.4.2 Long-Term Trends

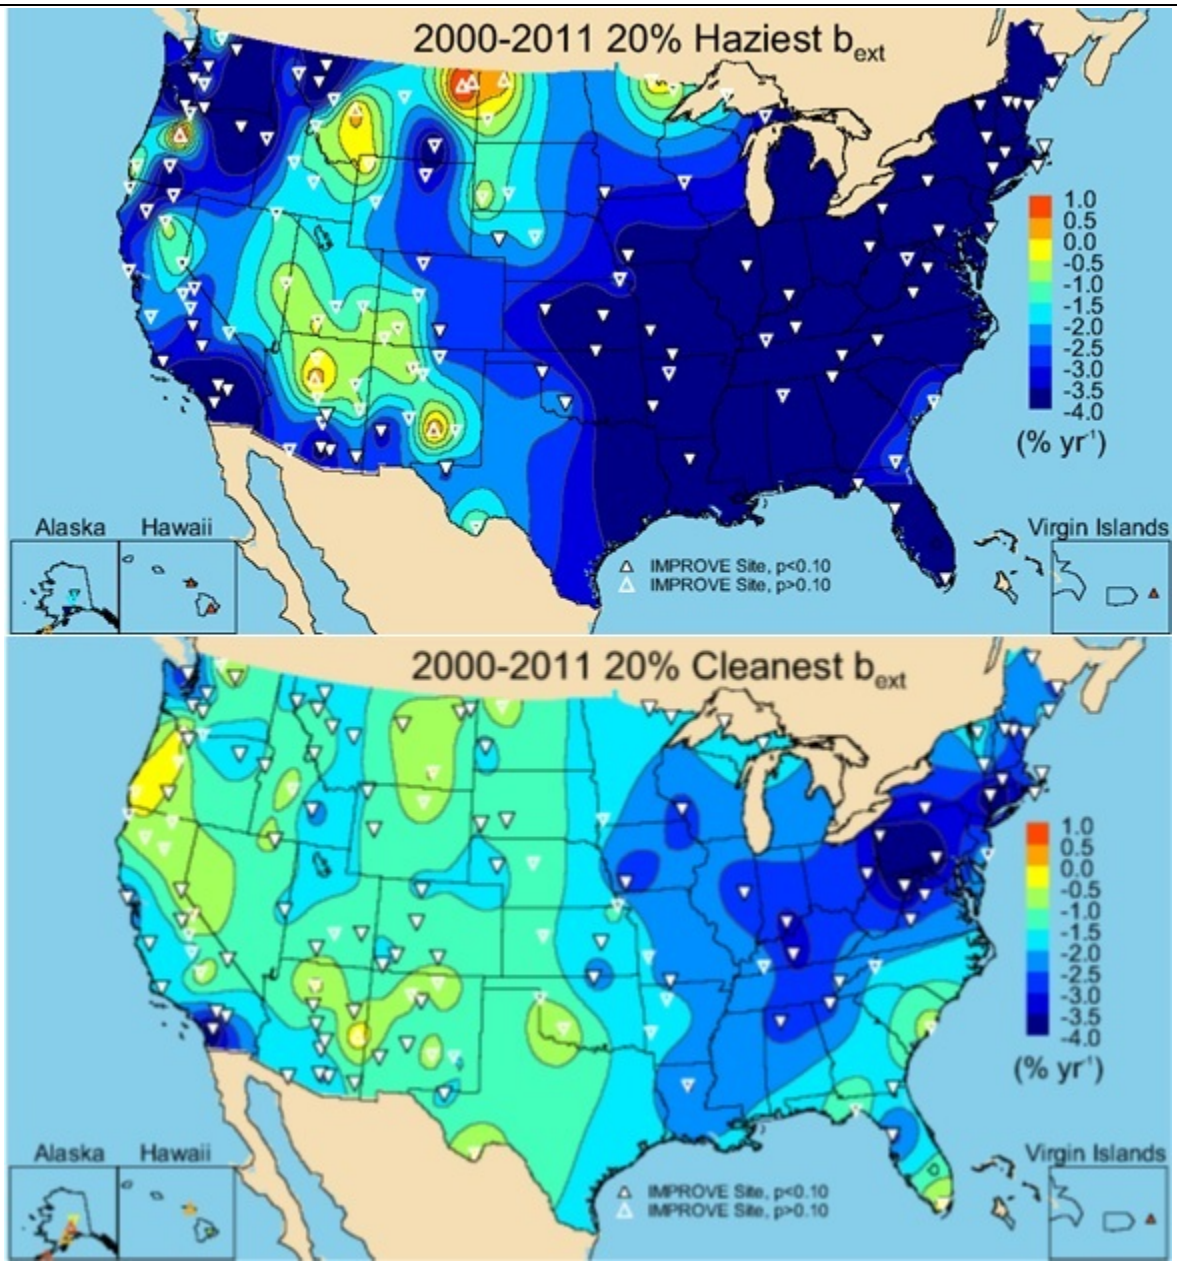
Long-term trends in atmospheric concentrations and visibility reduction since implementation of the IMPROVE network were reviewed in the 2009 PM ISA (U.S. EPA, 2009). Since that time there have been significant changes in the composition of atmospheric particulate matter in the U.S., described in detail in Chapter 2. On average, particulate ammonium sulfate (Hand et al., 2012b; Sickles and Shadwick, 2008), organic matter (Hand et al., 2013), light absorbing carbon (Murphy et al., 2011), and ammonium nitrate (Hand et al., 2011; Sickles and Shadwick, 2008) have decreased over the U.S. for both the IMPROVE and CSN monitoring data, resulting in decreasing $PM_{2.5}$ (Murphy et al., 2011) and haze (Attwood et al., 2014; Hand et al., 2014a).

The current Regional Haze Rule guidance documents require the tracking of haze in deciviews for the 20% worst and 20% clearest haze days (U.S. EPA, 2003, 2001). The trends in these haze metrics for 139 IMPROVE sites is presented in Figure 13-15 (Hand et al., 2014a). As shown, across the country, the 20% clearest days are less hazy (Hand et al., 2014a). Of the 139 sites, only three have upward trends compared to 136 downward trending sites. The largest downward trends were in the eastern U.S., where haze decreased by more than 3.5% per year in Pennsylvania and West Virginia. At the western sites, haze on the clearest days generally decreased 0.5–2%/year (Hand et al., 2014a).

The trends in the 20% worst haze days are somewhat different from those for the clearest days (Figure 13-15). As shown, in the eastern U.S., there have been steep declines in haze. All 54 sites east of −100-degree longitude had decreasing trends, and on average, eastern haze decreased 5%/year, or over 50% from 2000 to 2011. This large decrease was driven primarily by the reduction in ammonium sulfate (Hand et al., 2014a; Hand et al., 2012b). As illustrated in Figure 13-16 these reductions resulted in noticeably improved visibility at places like Great Smoky Mountains National Park and Washington, D.C. Improvements in visibility are also evident at many sites in the Pacific Coast states. This is not the case in the Intermountain and Southwest regions. These regions had 55 monitoring sites, and while a number of sites had increasing haze trends, none were significant. Fourteen of the 55 sites had significantly decreasing haze trends. These regions are subject to summertime wildfires, which have increased in the past decade. These wildfire events create high PM loadings and haze and often fall into the 20% haziest days (Hand et al., 2011). In northwestern North Dakota, wildfire is not a significant contributor to the worst haze days, and instead the increasing trends may be due to the rapid expansion of oil and gas extraction and the associated population growth (Prenni et al., 2015; Hand et al., 2012a). The range in annual b_{ext} values varies by about a factor of 10, with values above 70 Mm^{-1} in the Ohio River Valley region and less than 10 Mm^{-1} in the Southwest (Hand et al., 2011).

A recent revision to the Regional Haze Rule in 2017 clarified that haze should be tracked on the 20% most anthropogenically impaired days rather than the 20% haziest days to remove the influence of natural events like wildfire smoke and dust storms. Although a guidance document describing the method for determining anthropogenic impairment has not yet been finalized, a 2016 draft guidance recommended a metric which results in similar trend to Figure 13-15 for the Eastern U.S. but a decrease

in b_{ext} for the Intermountain and Southwest regions. The 2017 Regional Haze Rule revision did not change method of tracking haze for the 20% clearest days.



Note: Triangles correspond to IMPROVE sites; upward-pointing triangles correspond to increased b_{ext} and downward-pointing triangles correspond to decreased b_{ext}.

13.2.4.3 Characteristic Fine Particulate Mass Light Scattering Efficiencies

The effective $PM_{2.5}$ mass extinction efficiencies, i.e., b_{ext} to $PM_{2.5}$ concentrations vary depending on the $PM_{2.5}$ composition and relative humidity. Based on Equation 13-7 and Section 13.2.3, the PM components can be divided into three groups: 1) soil and coarse mass (low scattering efficiency); 2) organic mass and sea salt and associated water (mid scattering efficiency); and 3) ammonium sulfate nitrate and associated water, and EC (high extinction efficiency).

As discussed in Section 2.5 and Section 13.2.4.2, these PM components vary regionally and seasonally, as well as by urban versus rural settings. The ratio of the sum of PM component concentrations to light extinction by season averaged over the years 2011–2013 is presented in Figure 13-17. These values were calculated using the same procedures as in Hand et al. (2012a); Hand et al. (2011) listed in Table 13-3 and Equation 13-7. In general, regardless of season $PM_{2.5}$ b_{ext} is largest in the eastern half of the U.S. including the Northeast, Southeast, and Midwest, and lowest in the Southwest and interior portions of the Western U.S. A relatively high b_{ext} in urban areas, such as in the Northwest, and in those urban centers near the higher elevation rural sites in the Appalachian Mountains, is evident.

The average annual $PM_{2.5}$ extinction efficiency and standard deviation across all sites is 5.1 ± 1.1 m^2/g and a factor of 2.8 between the lowest and highest values. There is some variation in the $PM_{2.5}$ extinction efficiencies seasonally but the overall average and standard deviation across the seasons are similar to the annual values at 5.2 ± 1.3 m^2/g. These values are somewhat higher than reported in the literature and summarized in Table 13-1 possibly because of RH effects.

Figure 13-17 The effective $PM_{2.5}$ light extinction efficiency calculated as the ratio of the annual average reconstructed $PM_{2.5}$ b_{ext} and $PM_{2.5}$ concentrations.

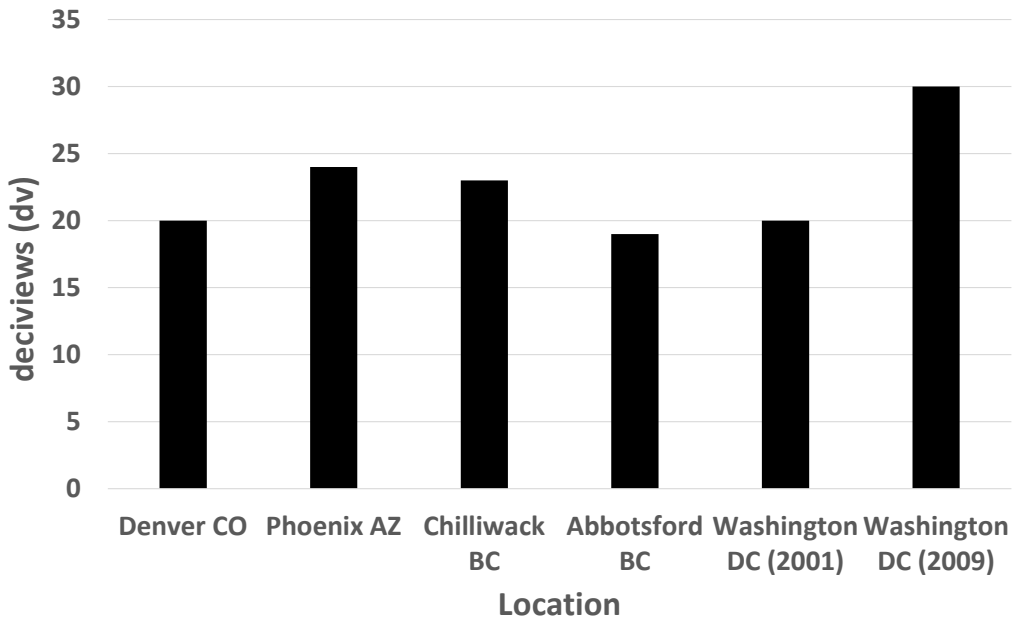
13.2.5 Human Perception of Haze and Landscape Features

The 2009 PM ISA (U.S. EPA, 2009) provided a detailed review of urban visibility preference studies from which haze and acceptability response curves were derived. Results indicated a wide range in the responses for a given deciview (dv) haze index (see Section 13.2.2.1) between urban areas, depending on their setting. Since then, no new visibility preference studies have been conducted in the U.S. Outside of the U.S., a visibility preference study was carried out in Beijing, China (Fajardo et al., 2013), but will not be further discussed because the high $PM_{2.5}$ concentrations in Beijing outside the range typically observed in the U.S.

As reported in the 2009 PM ISA (U.S. EPA, 2009), four North American urban visibility studies were conducted in Phoenix, Arizona (AZ-DEQ, 2003), two cities in British Columbia, Canada (Pryor, 1996), Denver, Colorado (Ely et al., 1991), and Washington, D.C. (Abt, 2001). The studies estimated the visibility preference, or level of visibility impairment judged acceptable, by respondents using a focus-group method with photographs of a single scene. A broad downtown area and hills or mountains making up the scene's backdrop were in each photograph. As described in U.S. EPA (2009), there was a large variance in the mean dv value for a preference of 50%, with 19 dv at Denver and 28 dv at Washington, D.C. The most distant landscape feature varied from 150 km away for the Denver scene to only 8 km away for the Washington, D.C., scene. The closer the landscape features are to the observer,

the more particulate matter, as represented by dv levels, it takes to cause the same level of perceived haziness. The deciview corresponding to 50% preference levels for each location is shown in Figure 13-18.

Figure 13-18 shows that considerably more haze was required to cause the Washington, D.C. scene to be judged unacceptable than the Denver scene. Between Washington, D.C. scene and the Denver scene there was a 9.2 dv difference in the amount of haze required for an unacceptable judgment at the 50% level, corresponding to about 30 μg/m^3 of particulate matter, assuming the particles are not hygroscopic. Consequently, it takes about 250% more particulate mass or b_{ext} to reach an unacceptable level of haze in the Washington, D.C. scene than in the Denver setting. In other scenes, the amount of haze required to be judged unacceptable was in between the amounts in Washington, D.C. and Denver.



Source: Permission pending, adapted from 2009 PM ISA U.S. EPA (2009).

Figure 13-18 Mean deciview (dv) values of 50% acceptability in 5 visibility preference studies (CO, AZ, BC, DC 2001, DC 2009).

These results clearly demonstrate a large range in dv or any transform of b_{ext} at a given level of acceptability, indicating these metrics are not universal indicators of visibility preference levels. For context, the 50% preference deciview range between 19 and 30 dv corresponds to a b_{ext} range of approximately 60 to 180 mM^{-1}, which can be compared to b_{ext} estimates by season and region in Figure 13-9, Figure 13-10, Figure 13-11, Figure 13-12, Figure 13-13, and Figure 13-14 in Section 13.2.4.3. Roughly half of the CSN regions evaluated in Section 13.2.4.3 had at least one monthly average b_{ext} estimate within that range in 2011−2014.

There is little new published information regarding preference levels in the U.S. The single new study by Smith (2013) was an investigation of "framing bias" in preference studies that can potentially occur because preference levels are chosen in part based on experimental variables such as number of photographs shown or range of the range of dv levels participants are shown when asked to state a preference about whether scenes in photographs are acceptable.

13.2.6 Summary and Causality Determination

Overall, visibility in most regions of the U.S. has improved since the 2009 PM ISA, as indicated by lower estimates of $PM_{2.5}$ mass extinction. The greatest improvements have occurred in the eastern half of the U.S., in regions with the poorest visibility. This has likely occurred because of a reduction in SO_2 emissions resulting in lower ammonium sulfate concentrations, because ammonium sulfate has historically accounted for a larger fraction of $PM_{2.5}$ mass than other $PM_{2.5}$ components, and also because ammonium sulfate is more effective than other $PM_{2.5}$ components at scattering light. The resulting decrease in $PM_{2.5}$ in the Eastern U.S. has resulted in better visibility.

Rural visibility impairment is greatest in Eastern U.S. regions, including the Southeast, East Coast, Mid-South, Central Great Plains, and Appalachian regions. In contrast, visibility is better on average in most regions of the Western U.S. Urban visibility is also generally better in the Western U.S. than in the Eastern U.S., with exceptions of urban areas in California and Alaska. In part, this reflects the difference in $PM_{2.5}$ composition between the East and West, with a greater fraction of ammonium sulfate in the Eastern U.S., and particulate organic matter in the Western U.S. The effectiveness of light extinction by $PM_{2.5}$ depends on composition and relative humidity, with low scattering efficiency from $PM_{10-2.5}$, moderate scattering efficiency by organic mass and sea salt, and high extinction efficiency by ammonium sulfate, ammonium nitrate, and light absorbing carbon. However, the difference in extinction between the Eastern U.S. and Western U.S. also reflects considerably higher $PM_{2.5}$ concentrations in the Eastern U.S. and California than in the rest of the Western U.S.

Altogether, new results and observations regarding atmospheric visibility provide evidence atmospheric visibility has improved as PM concentrations have decreased, that regional and seasonal differences in atmospheric visibility parallel regional and seasonal PM concentration patterns, and that regional differences in the relationship between PM and visibility are due to differences in PM

composition characteristics, rather than any factors beyond PM. These results confirm a well-established relationship between PM and visibility summarized in the 2009 PM ISA and earlier assessments. O**verall the evidence is sufficient to conclude that a causal relationship exists between PM and visibility impairment.**

13.3 Effects on Climate

13.3.1 Introduction

The 2009 PM ISA (U.S. EPA, 2009) concluded that there was sufficient evidence to determine a causal relationship between PM and climate effects—specifically on the radiative forcing of the climate system, and including both direct effects of PM on radiative forcing and indirect effects involving cloud processes. This section examines the role of anthropogenic PM in driving global and regional climate change, with a focus on the U.S. PM in the atmosphere significantly influences global and regional climate through interactions with incoming solar radiation and with clouds. For example, certain PM species reflect solar radiation back to space, leading to cooling at the Earth's surface. On the other hand, PM species that absorb solar radiation can heat the atmosphere and change the vertical temperature profile, with consequences for atmospheric stability, cloud formation, and convective rainfall. By providing cloud condensation or ice nuclei, PM can also influence cloud cover and affect the Earth's radiative balance, with additional impacts on the distribution and intensity of precipitation. Finally, because PM is not distributed evenly across the globe, spatial variation in these radiative and hydrologic impacts can also contribute to shifts in atmospheric circulation patterns over a range of space and time scales.

As the abundance of natural or anthropogenic PM changes over time, the effects on climate may be substantial. A key question for the scientific community is to what extent trends in anthropogenic PM have influenced climate through the 20th and early 21st centuries. Global trends in PM have varied by species. For example, U.S. emissions of SO_2, a precursor to sulfate PM, tripled from 1900 to 1980 (Smith et al., 2011), while black carbon (BC) emissions peaked in the early to mid-20th century (Bond et al., 2007). In more recent decades, as regulatory actions have been put in place to improve air quality, U.S. levels of sulfate and other PM species have declined rapidly (Keene et al., 2014; Murphy et al., 2011). The climate impacts of such trends are currently topics of intensive research (Fiore et al., 2015; Mickley et al., 2014; Bond et al., 2013; Boucher, 2013; Myhre, 2013).

Assessing the role of anthropogenic activity in past and future climate change is the mandate of the Intergovernmental Panel on Climate Change (IPCC), an initiative begun in 1988 by the World Meteorological Organization (WMO) and the United Nations Environmental Program. The IPCC supports the work of the Conference of Parties to the United Nations Framework Convention on Climate

Change (UNFCCC). New IPCC reports are issued every 5 to 7 years, and the climate discussion in the 2009 PM ISA (U.S. EPA, 2009) relied heavily on the Fourth IPCC Assessment Report (AR4), published in 2007. The Fifth IPCC Assessment Report (AR5) (IPCC, 2013) reports on the key scientific advances in understanding the climate effects of PM since AR4. This section thus accordingly draws substantially upon AR5 in summarizing these effects.

Section 13.3.2 provides an overview of the physics of climate as well as the metrics used to assess climate change (discussion of the models used to simulate climate, atmospheric chemistry, and the behavior of PM in the atmosphere is provided in Chapter 2). Section 13.3.3 describes the mechanisms of PM's influence on the Earth's energy budget. Sections 13.3.4 and Section 13.3.5 report the estimated radiative forcing for total PM and individual PM components, respectively. Section 13.3.6 describes the climate response to changing PM, including the feedbacks of climate onto PM abundance. Section 13.3.7 provides further details on the climate response to PM trends in specific U.S. regions, especially in the eastern half of the country, and Section 13.3.8 summarizes key uncertainties in gauging the role of PM in driving climate. Section 13.3.9 provides the final summary and causality determination. Note that, in the climate science community, PM is encompassed by what is typically referred to as aerosol (though the definitions do not completely overlap), but this section on the climate effects of PM uses the term PM throughout for consistency with the rest of this ISA. Exceptions to this practice include certain acronyms that are widely used by the climate community that include the term aerosol (e.g., aerosol optical depth, or AOD).

13.3.2 Overview of the Physics of Climate Change and Radiative Forcing

The Earth's climate is driven by energy from the sun. Radiant solar energy enters the atmosphere in a range of wavelengths, peaking strongly in the visible part of the spectrum. Approximately 70% of incoming solar energy is absorbed by the earth-atmosphere system, while the rest is reflected back to space, mainly by clouds and by snow- and ice-covered surfaces (Trenberth et al., 2009).

Atmospheric PM also interacts with incoming solar radiation. Many species of PM (e.g., sulfate and nitrate) are efficient scatterers of solar energy. By enhancing reflection of solar energy back to space, scattering PM exerts a cooling effect on the surface below. Certain species of PM such as BC, brown carbon (BrC), or dust can also absorb incoming sunlight. Whether absorbing PM warms or cools the underlying surface depends on several factors, including the altitude of the PM layer relative to cloud cover and the albedo of the surface (Ban-Weiss et al., 2014). PM also perturbs incoming solar energy by influencing cloud cover and cloud lifetime. For example, PM provides nuclei upon which water vapor condenses, forming cloud droplets. Finally, absorbing PM deposited on snow and ice can diminish surface albedo and lead to regional warming. More detailed information about these complex and sometimes competing effects of PM on climate is provided in Sections 13.3.3 and Section 13.3.4.

About two-thirds of the solar energy absorbed by the earth-atmosphere system is absorbed by the Earth's surface (Stephens et al., 2012; Trenberth et al., 2009). Much of that energy, in turn, is re-emitted at longer, infrared wavelengths, while some absorbed energy is also transformed into latent or sensible heat (Jung et al., 2011). Polyatomic gases such as water vapor, CO_2, methane, and ozone absorb and re-emit the infrared radiation upwelling from the Earth's surface, reducing the total amount of radiant energy that returns to space, keeping the surface and lower atmosphere substantially warmer than they would be in the absence of these gases. This heat trapping also contributes to further warming by increasing the concentration of water vapor, itself a strongly radiatively active gas, in the atmosphere, through increases in evaporation from the Earth's surface. In general, water vapor acts as an amplifier of the climate effects of other greenhouse gases; this process is one of the most important feedbacks in the climate system.

An important concept, used throughout this section, is "radiative forcing." Radiative forcing provides a simple way of characterizing and quantifying the net change in Earth's radiation budget resulting from a perturbation by one or more radiatively active atmospheric constituents, whether greenhouse gases, clouds, or PM species. Alternative definitions of radiative forcing (and related metrics), useful in different contexts, have been developed. The most relevant of these for the purposes of this ISA are defined below.

13.3.2.1 Observed Recent Climate Change: Detection and Attribution

Since the late 19th century, the global mean surface temperature of the Earth has warmed by ~0.85°C (Hartmann, 2013). The first decade of the 21st century represents the warmest decade in the instrumental record (Melillo et al., 2014), and 2016 was the warmest year globally (NOAA NCEI, 2017). Other indicators of climate change include a shrinking Arctic ice cap and a sharp decline in snow cover over North America, an increase in global-mean sea level by ~0.2 m since 1900, consistent with thermal expansion of ocean waters and diminishing glaciers in a warming climate, and an increase in average precipitation over the mid-latitude land areas of the northern hemisphere (Stocker, 2013). Detecting trends in climatological variables such as temperature, and attributing these trends to a given causal factor, such as increases in greenhouse gases or PM, first requires distinguishing them from natural climate system variability, and then evaluating the relative contributions of relevant causal factors to the trends, with appropriate measures of statistical confidence (Bindoff et al., 2013; Hegerl et al., 2010). Sensitivity studies using climate models have shown that the observed global temperature trends can be reproduced only when both natural and anthropogenic emissions of greenhouse gases, PM, and their precursors are taken into account (Jones et al., 2013). The IPCC concluded that, globally, anthropogenic forcings caused more than half of the warming for 1951−2010, with a likely contribution range of 0.6 to 0.7ºC (1.1ºF to 1.3ºF), compared with the observed warming of about 0.65ºC (1.2ºF) (Bindoff et al., 2013).

In general, detecting and attributing climate change—and projecting future change—is more difficult for regional scales compared to globally, for shorter time periods compared to longer ones, and for certain variables (e.g., precipitation) that are particularly "noisy" in space and time. This is because the natural variability over years and decades inherent in the climate system is relatively more important at these scales, compared to the forced signal of climate change, especially for some variables (Northrop and Chandler, 2014; Deser et al., 2012; Hawkins and Sutton, 2009). Nevertheless, it is possible to make some robust detection and attribution statements for North America and/or the U.S. For example, as with the globe as a whole, surface temperatures in the U.S. have also warmed, though with large spatial and temporal variation. Alaska has warmed most rapidly, by ~1.2°C since 1900 (Melillo et al., 2014). The continental U.S. warmed by about 0.9°C over this period, with most of the increase occurring after 1980 (Vose et al., 2012; Lawrimore et al., 2011). Over the time period 1930−1990, however, much of the Southeast experienced a net cooling of ~1°C, a trend that some studies have linked to changes in the concentration of anthropogenic PM (Yu et al., 2014; Leibensperger et al., 2012a, b), though others have suggested that internal climate system variability (Knutson et al., 2013; Meehl et al., 2012) or land-use change (Xu et al., 2015; Goldstein et al., 2009) was responsible. This cooling trend in the Southeast, which will be discussed in greater detail in Section 13.3.7, has since reversed to warming.

In addition to mean temperatures, heatwave frequency across the U.S. has also increased since the 1970s. For example, Meehl et al. (2009) found that the ratio of daily record high maximum temperatures to record low minimum temperatures in the U.S. is approximately two to one, a result confirmed in a more recent study (Meehl et al., 2016). With respect to precipitation, average annual precipitation over the U.S. has increased by roughly 5% since 1900, though with important regional differences (Melillo et al., 2014). Precipitation trends tend to be positive for the eastern and central states, with increases of as much as 10% since 1900 (McRoberts and Nielsen-Gammon, 2011). The western U.S., on the other hand, has recently experienced its most severe drought since the megadrought of 900−1300 A.D., although the connection to global climate change is uncertain (Griffin and Anchukaitis, 2014; Cook et al., 2010). The heaviest rainfall events, by contrast, have become heavier and more frequent across most of the U.S. For example, since 1991, the amount of rain falling in very heavy precipitation events has been significantly above average, with the greatest increases in the Northeast, Midwest, and upper Great Plains (Melillo et al., 2014).

13.3.2.2 Metrics of Climate Change, Including Radiative Forcing

Phenomena that perturb the Earth's energy system are known as climate forcing agents. When comparing the efficacy of one climate forcing agent against another it is useful to devise metrics to make such comparisons more systematically. While surface temperature change would seem to be an obvious choice for such a metric, the temperature response to a climate forcing agent is actually the net result of a cascade of feedback effects, both positive and negative, that can either amplify or diminish the initial temperature response to a given forcing (Myhre, 2013). The strengths of such feedbacks are not always

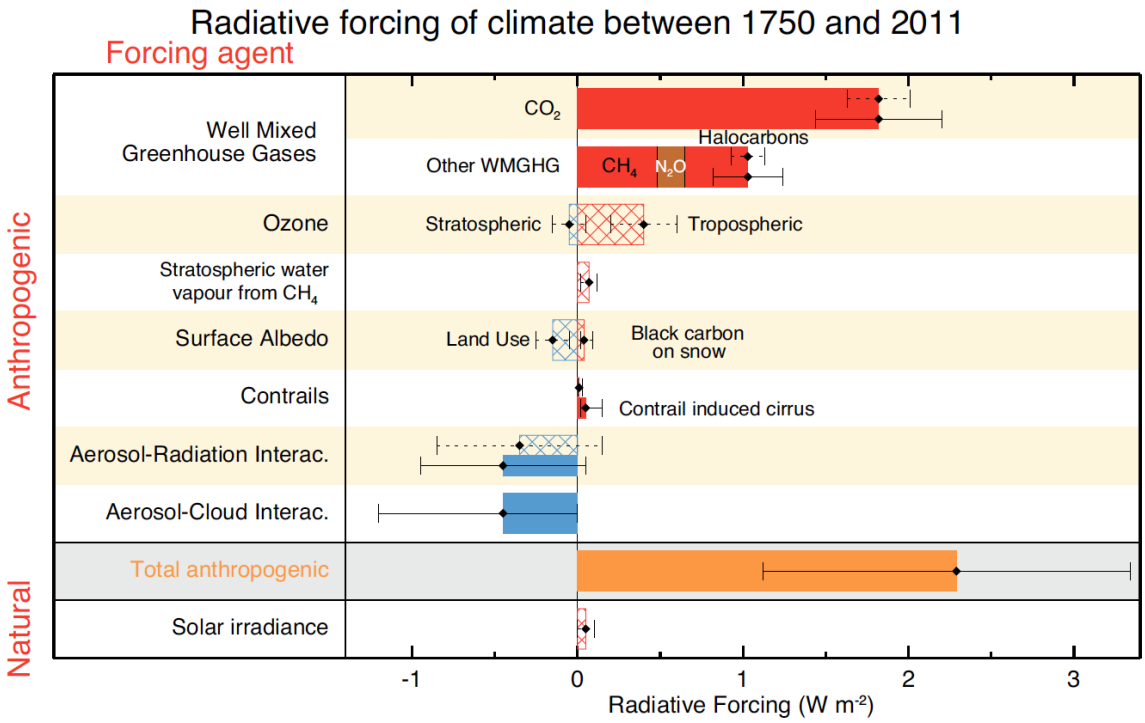
well constrained, making it challenging to use surface temperature as a metric of climate forcing agent efficacy, even with the use of climate models.

Four alternative metrics of climate change are identified below: radiative forcing (RF), effective radiative forcing (ERF), global warming potential (GWP), and global temperature potential (GTP). All four metrics are typically calculated with models; RF can also be estimated using a combination of models and satellite data. Of these metrics, RF and ERF provide the most direct descriptions of the radiative effects of PM in the climate system, and are therefore described in the most detail below (and will be focused on throughout the rest of this document). The definitions in this section draw heavily upon, and have been adapted from Myhre (2013) and Fiore et al. (2015).

Radiative forcing (RF) for a given atmospheric constituent is defined as the perturbation in net radiative flux, at the tropopause (or the top of the atmosphere), caused by that constituent, in Wm^{-2}, after allowing for temperatures in the stratosphere to adjust to the perturbation but holding all other climate responses constant, including surface and tropospheric temperatures (Fiore et al., 2015; Myhre, 2013). A positive forcing indicates net energy trapped in the Earth system and suggests warming of the Earth's surface, whereas a negative forcing indicates net loss of energy and suggests cooling. RF is typically classified according to wavelength, either shortwave (solar) or longwave (terrestrial). For PM, surface RF is also commonly reported, since haze events can significantly attenuate incoming solar energy, causing local "dimming."

For IPCC AR5, a new definition of RF was advocated, known as effective radiative forcing (ERF) (Myhre, 2013). ERF takes into account not just the instantaneous forcing but also a set of climate feedbacks, involving atmospheric temperature, cloud cover, and water vapor, that occur naturally in response to the initial radiative perturbation. These variables are allowed to adjust in the calculation of ERF. Climate system adjustments over longer timescales, e.g., involving sea surface temperatures and sea ice cover, are held constant in the calculation of ERF. An advantage of ERF for assessing the radiative forcing of PM is that, since it includes these rapid adjustments, the equilibrium change in global mean surface temperature scales more closely with ERF than with RF, making it more useful for analysis of the climate impacts of PM (Fiore et al., 2015; Myhre, 2013). A limitation of ERF is that quantifying it precisely depends on a robust understanding of all of the fast climate feedback processes. The response of clouds in particular to changing climate is, however, highly uncertain (Zhao et al., 2016; Soden and Vecchi, 2011), as will be discussed in more detail below.

The global mean values of RF and ERF are important indicators of the climate response to a given perturbation. Figure 13-19 shows the IPCC AR5 estimates of RF and ERF over the 1750−2011 timeframe for a range of anthropogenic climate forcers. For PM and other short-lived species, however, the temporal and spatial variation in such forcings can vary by orders of magnitude. For example, for a severe pollution event over the North China Plain in 2013, Che et al. (2014) reported large RFs from PM of as much as -60 Wm^{-2} at top of atmosphere (TOA) and $+200$ Wm^{-2} at the surface over several days (in comparison, for example, with the long-term, globally averaged values shown in Figure 13-19).



Note: Radiative forcings (RFs) are shown as hatched bars and effective radiative forcings (ERFs) are shown as solid bars. Uncertainties (5% to 95% confidence range) are indicated by dotted lines for RF and solid lines for ERF. Positive forcings denote warming of the Earth's surface, whereas negative forcings denote cooling. WMGHG refers to the well-mixed greenhouse gases, and aerosols refers to PM. The abbreviation "interac." means "interactions."

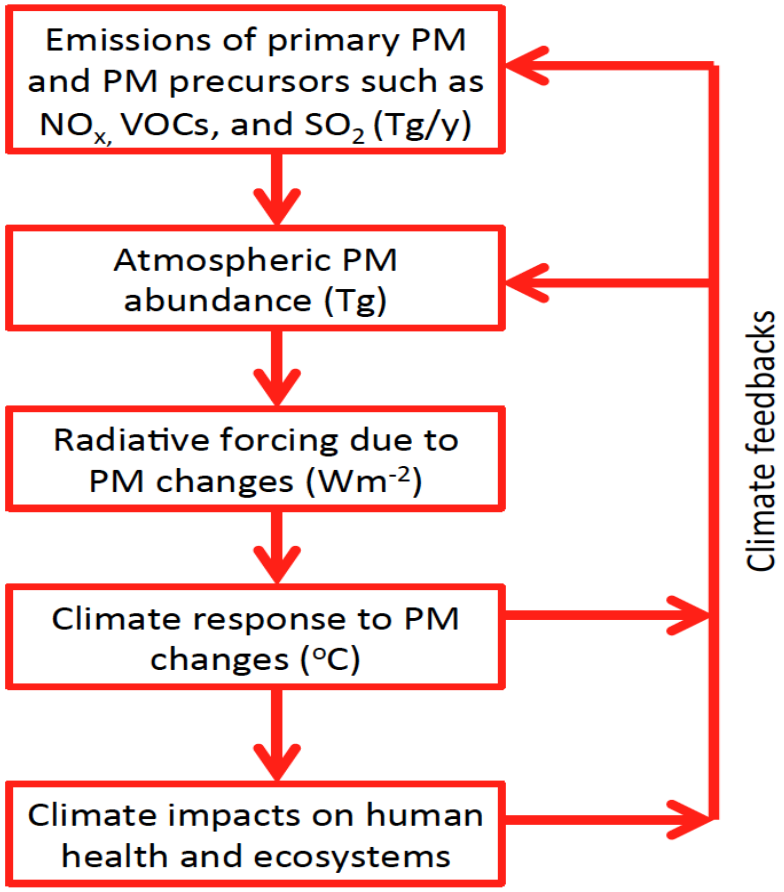
Figure 13-19 Global mean radiative forcing from anthropogenic activities from 1750 to 2011.

Two other metrics, GWP and GTP, are also sometimes used. Briefly, GWP is used to compare the climate impacts of a given atmospheric constituent to those of CO_2, taking into account not just the warming (or cooling) effects but also the constituent's atmospheric lifetime. GWP is defined as the integral over a specified time horizon (generally 20, 50, or 100 years) of the global mean RF arising from an emission pulse of a given constituent, normalized by the corresponding integral for an emission pulse of the same mass in CO_2 (Fiore et al., 2015; Myhre, 2013). GTP similarly assesses the effect of a climate forcing agent on surface temperature at a specific time horizon, but based on the surface temperature at the final timestep rather than as an integral. Both GWP and GTP have methodological or computational issues that make them less useful than RF or ERF for estimating the radiative impacts of PM.

The IPCC currently promotes the use of ERF over RF (Myhre, 2013), but not all published papers report ERF. The remainder of this section will therefore focus on RF and, when available, ERF of atmospheric particles. Figure 13-20 diagrams the links between PM sources, atmospheric abundance, radiative forcing, and the resulting climate response. Also illustrated in the figure are feedbacks between PM effects on climate and the ecosystem and PM sources and abundance. The nonuniform spatial and temporal distribution of PM and its constituent species compared to well-mixed greenhouse gases presents significant challenges for designing metrics able to capture the full range of global and regional climate forcing effects of PM. Some research on regional metrics [e.g., (Aamaas et al., 2016; Shindell, 2012)] and responses to regional forcings (Shindell et al., 2012; Shindell and Faluvegi, 2009) has been conducted to date, and additional research is currently ongoing.



Note: This figure depicts the relationships between PM sources, PM abundance, radiative forcing, climate response, and climate impacts. Units shown are those typical for each quantity illustrated. VOCs stands for volatile organic compounds. Feedbacks from both the climate response and climate impacts on ecosystems can affect both the emissions of PM sources and PM atmospheric abundance through multiple mechanisms.

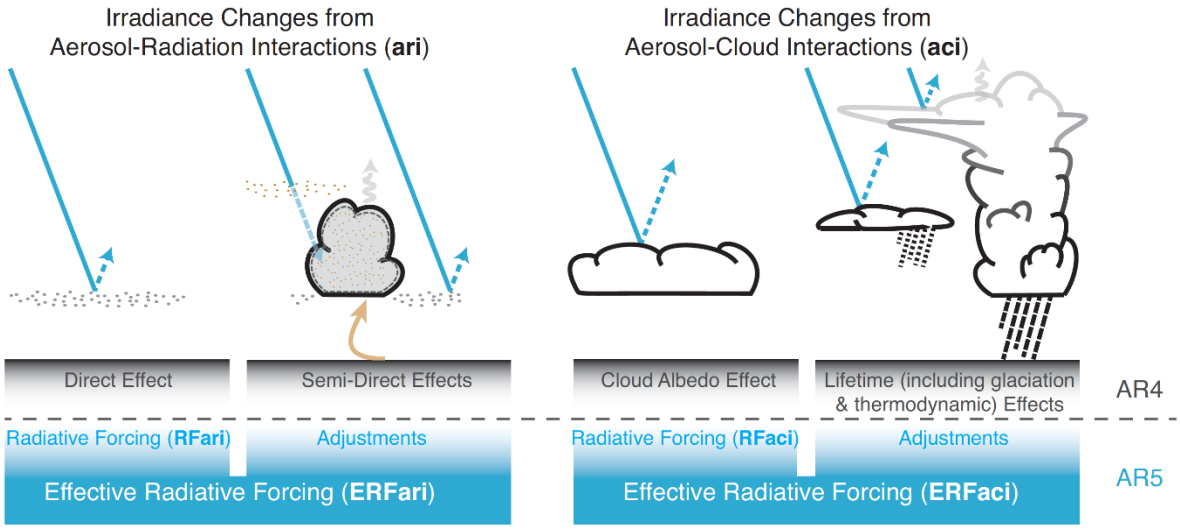
Figure 13-20 Schematic illustrating the effects of PM on climate.

13.3.3 Effects of PM on Radiative Forcing: Mechanisms

As introduced at the beginning of Section 13.3, PM radiative forcing, both through direct interactions with incoming solar radiation, and through interactions with clouds, affects surface and atmospheric temperatures, with subsequent impacts on precipitation and circulation patterns. This section describes the main mechanisms of PM impact on radiative forcing, including the influence of particle size on these mechanisms. The next two sections summarize quantitative estimates of PM radiative forcing globally for total PM, and by individual PM species, respectively. Later sections discuss the global and regional climate impacts of this PM radiative forcing, climate feedback mechanisms involving PM, and key sources of uncertainty in assessing these radiative and climate effects.

13.3.3.1 Interactions of PM with Radiation

Atmospheric PM interacts with solar radiation through scattering and absorption. These "aerosol-radiation interactions" (ARI) are also known as the "direct effects" of PM on climate, as opposed to the "indirect effects" that involve PM interactions with clouds (Section 13.3.2.2). The IPCC AR5 devised the acronym RFari to refer to radiative forcing due to ARI (Boucher, 2013). The fate of solar energy intercepted by PM, and thus the magnitude and sign of RFari, depends on the optical properties of the particles. Highly reflective PM such as sulfate scatter the incoming solar energy, with much of that energy returning to space. Highly absorbing PM such as BC convert solar energy to heat. A metric known as the single scattering albedo represents the ratio of the scattering cross section to the sum of scattering and absorbing cross sections for a given PM type and wavelength. The single scattering albedo for sulfate approaches 1.0. The water content and size distribution of PM can significantly also affect the scattering efficacy of PM. Figure 13-21 depicts the mechanisms of RFari, as well as the effective radiative forcing due to ARI (ERFari), which includes the fast meteorological responses to RFari (as described in Section 13.3.2.2 above).



Note: The blue arrows represent solar radiation, the gray arrows represent cloud longwave radiation, and the brown arrow symbolizes the coupling between the surface and the cloud layer that occur on rapid timescales. The left-hand panel depicts aerosol-radiation interactions (ari) and associated forcings: radiative forcing (RFari) for the direct effect and effective radiative forcing (ERFari) for the direct effect plus rapid meteorological adjustments. The right-hand panel shows aerosol-cloud interactions (aci) and associated forcings: radiative forcing (RFaci) for the cloud albedo effect and (ERFaci) for the cloud albedo effect plus rapid meteorological adjustments. Also shown are the equivalent terms for these effects and adjustments in IPCC AR4. See text for further details.

Figure 13-21 Schematic of mechanisms by which PM affects climate and the terminology used in the Intergovernmental Panel on Climate Change (IPCC) Fifth Assessment Report (AR5) to categorize PM radiative forcings.

Reflective PM, by sending a fraction of solar energy back to space, has an overall cooling effect on global climate. In contrast, absorbing PM has an overall warming effect on global climate, and the in situ warmth generated by solar absorption can be transported elsewhere in the atmosphere. Regardless of species type, PM generally cools the underlying surface through attenuation of solar radiation. Absorbing PM can also have complex and sometimes competing effects on regional hydrological cycles, with consequences for the Earth's energy budget. For example, in their model study, Koch and Del Genio (2010) found that BC particles embedded within clouds warm the local atmosphere and reduce cloud cover, while those located above clouds stabilize the atmosphere, enhancing stratocumulus clouds (semidirect effects). When all these effects are considered together, PM has a net cooling effect on global climate (Fiore et al., 2015; Myhre, 2013), as will be discussed in more detail below.

13.3.3.2 Interactions of PM with Clouds

By providing cloud condensation nuclei, PM increases cloud droplet number and thus cloud droplet surface area and albedo (Twomey, 1977). The climate effects of these perturbations are difficult to quantify but likely enhance the cooling influence of clouds by increasing cloud reflectivity (traditionally called the first indirect effect) and lengthening cloud lifetime (the second indirect effect). Such effects can be difficult to distinguish in the observational record, in part because they likely feed back onto one another (Rosenfeld et al., 2014). The IPCC AR5 defines the first indirect effect as "radiative forcing due to aerosol-cloud interactions" (RFaci), and includes the second indirect effect within "effective radiative forcing due to aerosol-cloud interactions" (ERFaci), which accounts for rapid adjustments in temperature, precipitation, and cloud lifetime. Figure 13-21 depicts the mechanisms of RFaci and ERFaci (Boucher, 2013).

Quantifying RFaci is challenging because it includes the impacts of a complex suite of meteorological and chemical variables (e.g., relative humidity, cloud updraft velocity, and mixing state) on microphysical cloud processes, most of which are not well captured in coarse-grid climate models (Ban-Weiss et al., 2014). Another difficulty involves establishing a baseline for RFaci in the natural atmosphere. For example, Schmidt et al. (2012) showed that the effect of volcanic PM on cloud albedo results in a -1.0 Wm^{-2} cooling in a pristine environment, but only half that value is achieved in the polluted present-day environment, when more PM are competing for the available water vapor. Still more complex to quantify is ERFaci, which includes the fast meteorological feedbacks to the interactions of PM with clouds. These uncertainties associated with aerosol-cloud interactions and feedbacks (discussed throughout the rest of this chapter section) present to the most significant obstacle to more precisely quantifying the effects of PM on climate.

13.3.3.3 Effects of Absorbing PM on Snow and Ice Albedo

Regions of high albedo, such as snow- and ice-covered surfaces, strongly reflect incoming solar radiation. The transport and subsequent deposition of absorbing PM such as BC to snow- and ice-covered regions can decrease the local surface albedo, leading to surface heating. The absorbed energy, in turn, can melt the snow and ice cover and further depress the albedo, resulting in a positive feedback loop (Bond et al., 2013; U.S. EPA, 2012). This feedback has been invoked to partly explain the rapid increase in temperatures over the Arctic relative to the increase over mid-latitudes [e.g., (Shindell and Faluvegi, 2009)]. BC deposition may also affect surface temperatures over glacial regions. For example, ice core records from the Tibetan plateau indicate at least a doubling in the deposition rates of absorbing species since preindustrial times, with the potential to contribute to increased future melting of the Tibetan glacier (Wang et al., 2015). Recent observations have also shown that dust particle deposition on mountain snowpack strongly controls snowmelt-driven runoff in the Upper Colorado River Basin (Painter et al., 2018).

13.3.3.4 Effect of Particle Size on the Interactions of PM with Climate

The size of particles influences how they interact with climate. Particles with diameters in the size range of 0.1−1.0 μm efficiently scatter solar radiation because they are within the same size range as the wavelength of solar energy. Thus $PM_{2.5}$, with diameter less than 2.5 μm, is more scattering and leads to greater surface cooling than the larger size fraction of $PM_{10–2.5}$. Most anthropogenic particles (e.g., sulfate and nitrate) fall within the $PM_{2.5}$ classification. Freshly emitted BC, BrC, and dust tend to be larger in size, though the smaller particles of these species have a disproportionately large radiative impact despite the total mass being dominated by the coarse mode (Boucher, 2013). Large particles have a relatively short lifetime and deposit quickly, leaving finer particles to travel further distances and extend their climate impact over a broader region. Large BC particles, however, can coagulate and then collapse into more compact and longer-lived structures (Raes et al., 2000). When exposed to high relative humidity, PM can take up water, deliquesce, and increase in size. As they age and acquire more hydrophilic coatings, even hydrophobic particles such as BC or dust can swell with water. Deliquesced particles tend to scatter more light than solid particles (Freney et al., 2010).

With regard to interactions of PM with clouds, laboratory experiments and model results show that particles with diameters in the range of 0.1−1.0 μm serve as efficient cloud condensation nuclei (Zhang et al., 2002). Thus $PM_{2.5}$ is a key contributor to such interactions. While UFP have traditionally been considered too small to influence cloud formation, they can rapidly grow into the size range required for cloud droplet activation, and so also play an important role in influencing cloud cover (Lee and Adams, 2012). In addition, there is now some evidence that UFP can themselves increase cloud condensation within tropical deep convective cloud systems (Fan et al., 2018). Coarse particles ($PM_{10–2.5}$), on the other hand, make a relatively small contribution to the number concentrations of cloud condensation nuclei, in part because key microphysical processes may occur over longer timescales than the typical residence time of such particles, and in part because $PM_{10–2.5}$ is less abundant (Raes et al., 2000). Mineral dust PM is a particularly important source of ice nuclei (IN) in cold clouds (Atkinson et al., 2013). Models attempting to capture the effects of PM on cloud cover and cloud lifetime often rely on cloud microphysical schemes with size-resolved particles (Pierce and Adams, 2007).

13.3.4 Estimates of Radiative Forcing from Total PM

This section discusses estimates of the forcing due to the sum of all PM species, including trends since the preindustrial era and since 1980. Table 13-4 summarizes this information.

Table 13-4 Estimates of global mean radiative forcings due to anthropogenic PM.

Reference	Forcing Agent and/or Time Period	Radiative Forcing RF, Wm^{-2}	Effective Radiative Forcing ERF, Wm^{-2}	Data Type

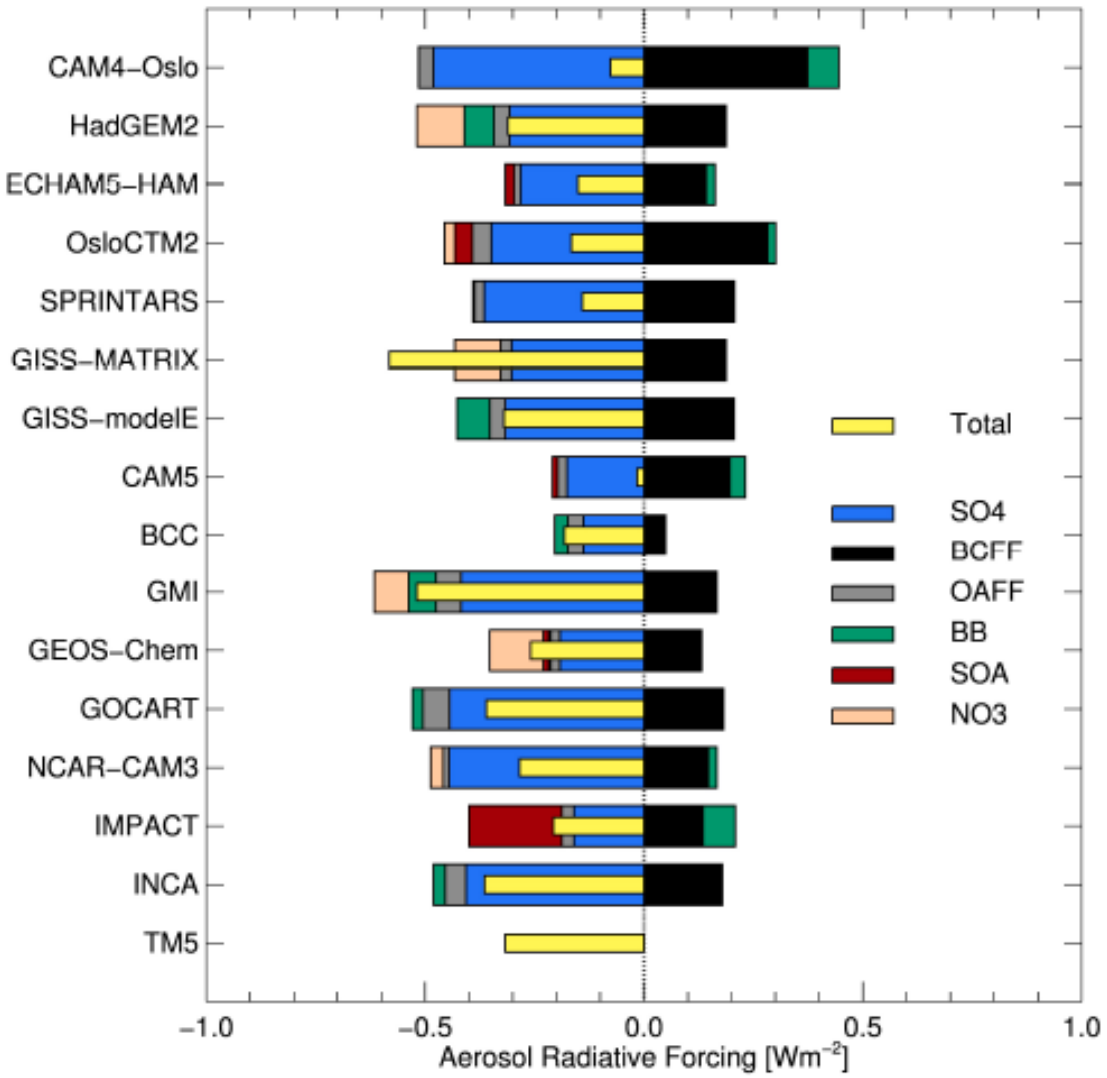
[a]Excludes the effects of absorbing PM on surface albedo.

13.3.4.1 Forcing Due to Interactions of PM with Radiation

Historically, reflective PM have dominated absorbing PM in terms of forcing, leading to net global cooling and a negative RFari since the preindustrial era (Allen et al., 2013; Myhre, 2013). Koch et al. (2011) calculated a global mean value of −0.41 Wm^{-2} for the change in anthropogenic PM since 1900, while the AeroCom international model intercomparison study reports a value of −0.27 Wm^{-2} for the change since 1850, with values ranging from −0.58 to −0.02 Wm^{-2} across the ensemble of models considered (Myhre et al., 2013). Figure 13-22 shows the range of model estimates for total forcing and for individual species in the AeroCom ensemble. The large uncertainty in the AeroCom RFari arises in part from the neglect in some models of nitrate particles and SOA. Those models that do include SOA demonstrate a large range of forcing values for this particle type, and the range of positive forcings from fossil fuel BC is also large (Myhre et al., 2013). Adjustment of the AeroCom average to extend the time

horizon and to take into account species missing from some models yields a mean RFari of −0.35 Wm^{-2} over the period since 1750 (Myhre et al., 2013).

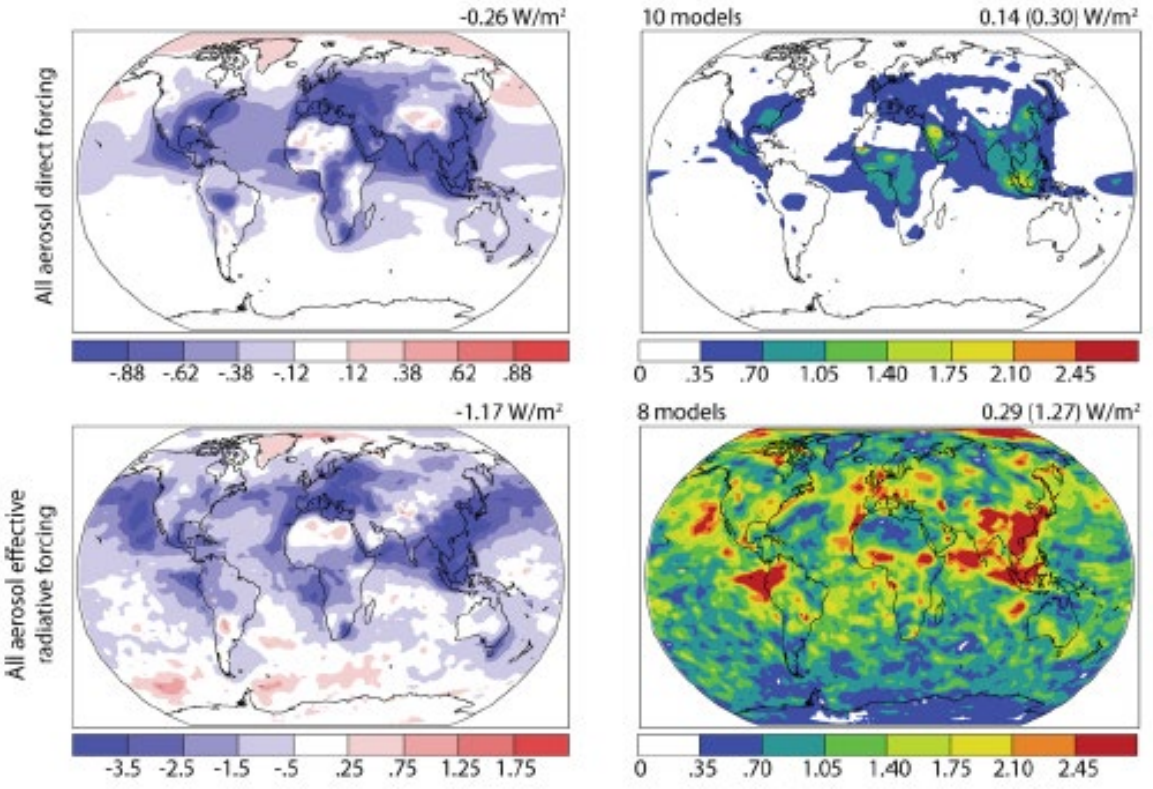


Note: The time period of the forcing is 1850 to 2000 or 2006, depending on the model, and the six components are sulfate (SO_4, blue), BC from fossil fuel (BCFF, black), organic particles from fossil fuel (OAFF, grey), biomass burning particles (BB, green), secondary organic particles (SOA, red), and nitrate (NO_3, brown).

Source: Permission pending, Myhre et al. (2013).

Figure 13-22 Radiative forcing from PM interactions with radiation (RFari) from six PM components in the AeroCom ensemble of models, overlain with total RFari for each model (yellow).

The ACCMIP model ensemble similarly shows a range of estimates for RFari, −0.26 (−0.06 Wm^{-2} to −0.49) Wm^{-2} (Shindell et al., 2013). Figure 13-23 shows the spatial distribution of the mean and standard deviation of RFari across the ACCMIP models. In general, RFari is greatest over regions of industrial activity—the eastern U.S., Europe, and Asia. As in the AeroCom study, the distribution of standard deviation in Figure 13-23 reveals the large disagreements among models in forcing magnitude.



Note: The top panels show the multimodel mean (left) and standard deviation (right) of forcing due to interactions of particles with radiation (RFari), also known as "direct forcing." The bottom panels show the multimodel mean (left) and standard deviation (right) of total effective radiative forcing due to interactions of PM with both radiation and clouds (ERFari+aci). ERF includes fast feedbacks involving clouds, atmospheric temperature, water vapor, and land albedo. Note the difference in color bars for RFari and ERFari+aci.

Figure 13-23 Spatial distributions of radiative forcing due to changing PM from 1850 to 2000 in the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) model ensemble.

Until recently satellite studies yielded more negative RFari forcings than did models, especially over land, for reasons that were not clear. For example, using remotely sensed data from the Moderate Resolution Imaging Spectroradiometer (MODIS), Bellouin et al. (2008) estimated a present-day RFari

from anthropogenic PM of −0.65 Wm^{-2}. Quaas et al. (2008) combined satellite data with model simulations to determine an even more negative RFari of −0.9 Wm^{-2}. This discrepancy was largely reconciled in Myhre (2009) by accounting for both direct radiative forcing missing from satellite retrievals and differences in aerosol optical properties between preindustrial and the present-day, bringing both the satellite- and model-based methods into agreement at the less negative values of RFari characteristic of model-based approaches.

Therefore, taking into account both model simulations and satellite observations, the IPCC AR5 reports an RFari from anthropogenic PM of −0.35 ± 0.5 Wm^{-2} (Boucher, 2013), which is slightly reduced in magnitude compared to AR4. Estimates of ERFari, which include the rapid feedback effects of temperature and cloud cover, rely mainly on model simulations, as this forcing is complex and difficult to observe. The IPCC AR5 best estimate for ERFari, −0.45 ± 0.5 Wm^{-2}, reflects this uncertainty (Boucher, 2013). Recall Figure 13-19, which shows the IPCC AR5 estimates of RFari and ERFari over the 1750−2011 timeframe, compared with other anthropogenic forcings.

13.3.4.2 Forcing Due to Interactions of PM with Clouds

Using data from a suite of satellite observations together with the AeroCom ensemble of models, Quaas et al. (2009) estimated RFaci at −0.7 ± 0.5 Wm, while climate models contributing to the IPCC AR5 yield a median value of −1.4 Wm^{-2} for anthropogenic RFaci (Boucher, 2013). ERFaci is difficult to quantify since it requires distinguishing between the feedbacks arising from interactions of PM with clouds and those arising from PM interactions with radiation. IPCC AR5 estimates ERFaci at −0.45 Wm^{-2}, with a 90% confidence interval of −1.2 to 0 Wm^{-2}.

13.3.4.3 Total Radiative Forcing Due to Interactions of PM with Clouds and Radiation

Using a cloud-resolving model embedded in a global climate model, Wang et al. (2011a) calculated an ERFaci+ari of −1.05 Wm^{-2}. Murphy et al. (2009) analyzed the Earth's energy balance and derived a similar value, −1.1 Wm^{-2}, while the ACCMIP ensemble of models yields an ERFari+aci of −1.17 (−1.44 to −0.71) Wm^{-2} (Shindell et al., 2013). Broadly consistent with these estimates, the IPCC AR5 reports a best estimate of ERFaci+ari of −0.90 (−1.9 to −0.1) Wm^{-2} (Boucher, 2013). As shown in Figure 13-19, which compares the IPCC AR5 estimates of ERFari and ERFaci over the 1750−2011 timeframe with other anthropogenic forcings, most of the uncertainty in total anthropogenic forcing since 1750 arises from uncertainties in the PM forcings. Figure 13-23 (bottom panels) shows the spatial distribution of ERFari+aci, with large forcings extending over oceans, where PM can strongly influence marine cloud cover downwind of source regions (Shindell et al., 2013).

13.3.4.4 Forcing Due to the Effects of Absorbing PM on Albedo

Recent estimates of the global mean RF from anthropogenic PM deposited on highly reflective surfaces such as snow and ice range from +0.01 to +0.04 Wm^{-2} (Bond et al., 2013; Lee et al., 2013; Skeie et al., 2011; Flanner et al., 2007). The IPCC AR5 reports a best estimate of RF from the albedo effect at the high end of this range, +0.04 Wm^{-2}, with an uncertainty range of +0.02 to +0.09 Wm^{-2} (Boucher, 2013). Table 13-1 contains a summary of these results, and Figure 13-23 (bottom right) shows the spatial distribution of this forcing from ACCMIP. As with other forcings, the uncertainty stems in part from uncertainties in emissions and in transport processes, including wet deposition (Doherty et al., 2010). The forcing is largest during March-May over the Arctic and boreal regions due to efficient winter-spring transport of pollution from Eurasia (Flanner et al., 2007).

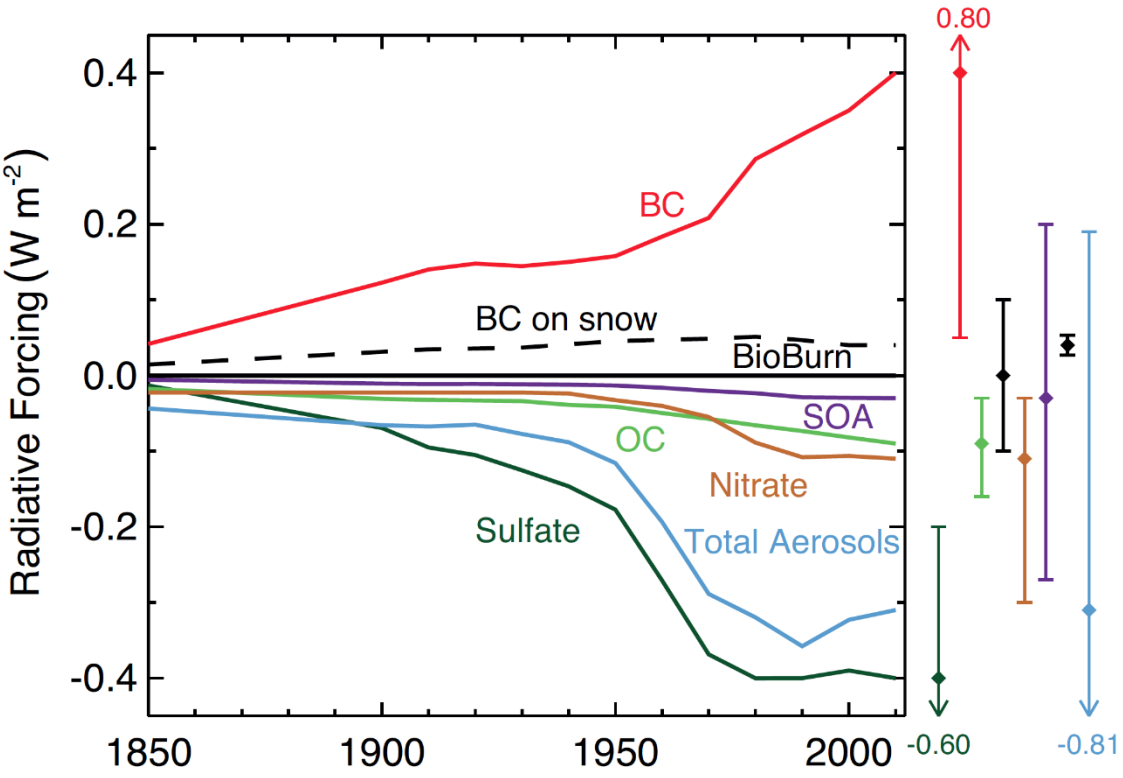
13.3.4.5 Recent Trends in PM Forcing

In response to air quality concerns, most developed countries have made significant cuts to emissions of PM or their precursors in recent decades, and this trend is revealed in the time series of forcing estimates for the 20th century. For example, in the ACCMIP ensemble of models, trends in global mean RFari for all PM species show maximum cooling around 1980, but with a large uncertainty range, from about −0.1 to −0.5 Wm^{-2} (Shindell et al., 2013). Smith and Bond (2014) estimate that the largest total impact of absorbing and scattering aerosols on climate occurred between 1950 and 1970, with a change in total aerosol forcing over this period ranging from −0.2 to −0.8 W m^{-2}. Major sources of uncertainty in these types of estimates of trends in aerosol radiative forcing include uncertainties in the temporal changes in emissions and in the mix of scattering versus absorbing aerosols (Xing et al., 2015; Smith and Bond, 2014).

Figure 13-24 shows the time evolution of RFari for a range of species from 1850 to 2010. In Figure 13-25 (top), the spatial distribution of the 1980−2000 forcing trend from the sum of all species reveals large heterogeneity. RFari is positive over North America and Europe due to declining sulfate loading in the time period. In contrast, RFari increases significantly over India and southeast Asia, where rising concentrations of reflective sulfate outpace those of the more absorbing BC. Over China, however, the increases in sulfate and BC loadings are more balanced, leading to an RFari close to zero for this time period. The positive RFari over Africa can be traced to increases in biomass burning and the subsequent rise in BC (Figure 13-25, bottom).

The forcings depicted in Figure 13-24 and Figure 13-25 are all TOA forcings. At the TOA, the effects of absorbing and scattering particles can cancel each other out, while at the surface, the effects of both types of particles combine to yield net cooling. For example, while China shows no TOA forcing over the 1980−2000 in Figure 13-25, another study suggests that increases in BC and sulfate particles

over this region have led to a cooling trend of -6 ± 2 Wm^{-2} per decade over the 1950–2000 time frame (Folini and Wild, 2015).



Note: The curves show the multimodel results for 1850, 1930, 1980, and 2000 from the ACCMIP ensemble for RFARI (Shindell et al., 2013) and the BC-albedo effect (Lee et al., 2013), combined with higher temporal-resolution results from two models in the ensemble. The blue curve represents the sum of all forcings shown. The 5% to 95% uncertainty ranges for 2010 are shown with vertical lines to the right of the graph. Values next to the uncertainty lines are for cases in which uncertainties go beyond the scale. All values have been scaled to the best estimates for 1750–2011 RFARI. SOA is for secondary organic particles, and "bioburn" represents the sum of RFARI of BC and primary organic particles from biomass burning. Estimates of forcings from mineral dust are not shown.

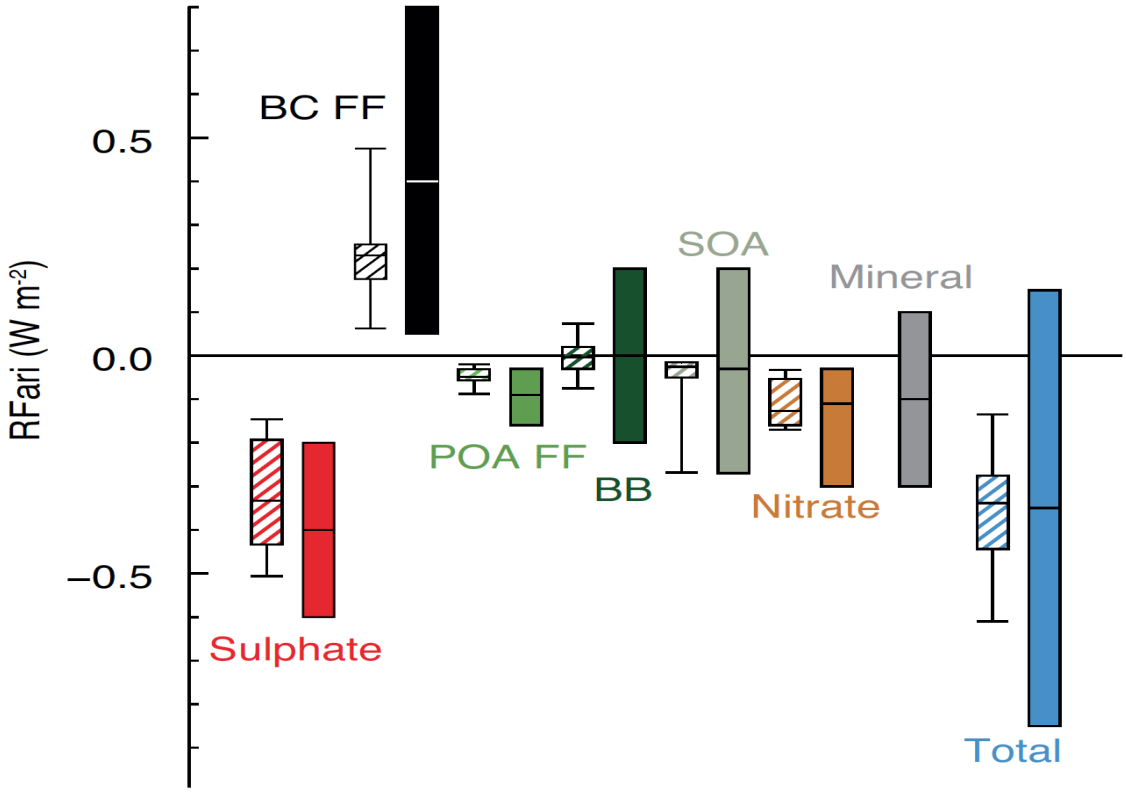
13.3.5 Effects of PM on Climate by Species

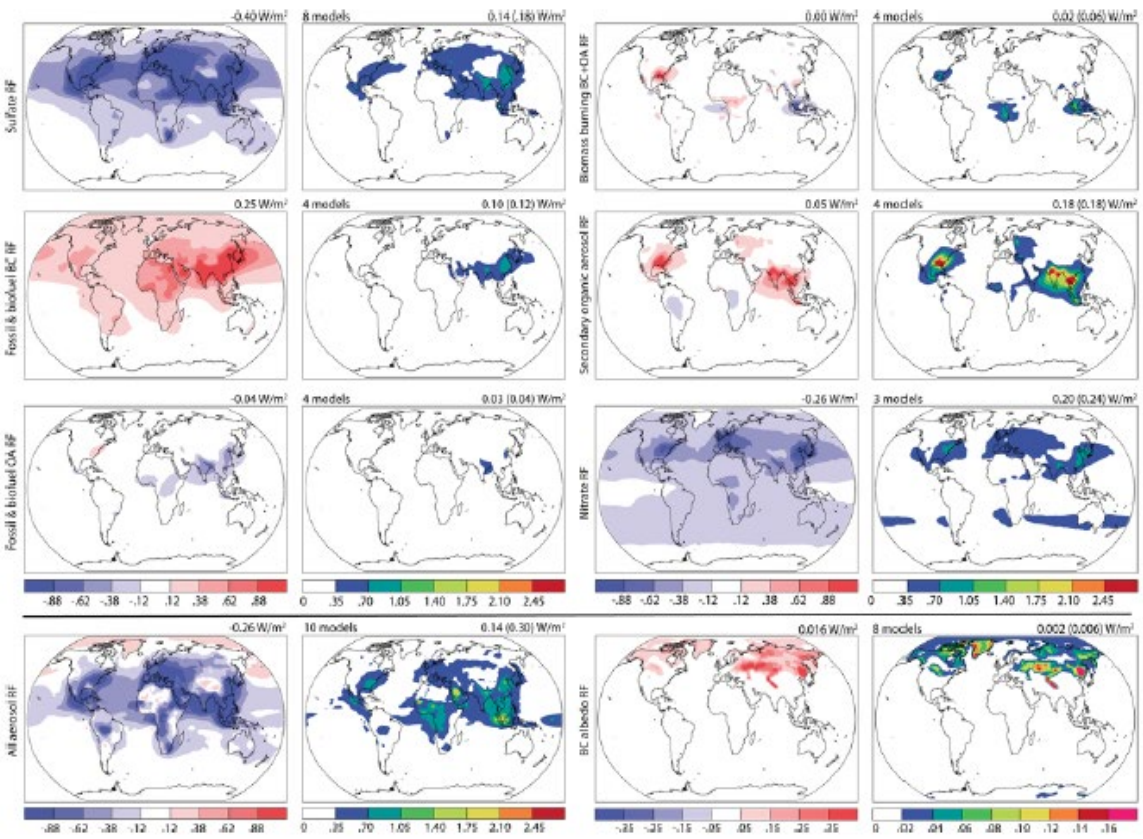
This section describes the individual climate effects associated with the following key PM species: sulfate, nitrate, OC, BC, and dust, to the extent that quantitative estimates of the radiative forcing associated with these individual species are available in the literature. Figure 13-26 shows the AeroCom and IPCC AR5 estimates of the annual mean TOA RFari for these different PM species discussed below. Figure 13-27 shows the global spatial distributions of the forcings by species type, as calculated in the ACCMIP ensemble.



Note: These interactions are also known as aerosol-radiation interactions (RFari), and values of RFari for different PM species are shown. Units are Wm^{-2}. Hatched boxes show results from an AeroCom model study, adjusted for the 1750–2010 period, with boxes denoting the 5% to 95% uncertainty ranges and whiskers denoting the minimum and maximum values across models (Myhre et al., 2013). Solid colored boxes show the IPCC AR5 best estimates and the 5% to 95% uncertainty ranges. BC FF indicates black carbon from fossil fuel and biofuel; POA FF, primary organic PM from fossil fuel and biofuel; BB, biomass burning PM; and SOA, secondary organic PM.

Source: Permission pending, Boucher (2013).

Figure 13-26 Estimated annual mean top-of-the-atmosphere radiative forcings due to interactions of PM with radiation for the 1750–2010 period.



Note: The top three rows show the forcings due to PM interactions with radiation (RFari) for different PM species, the bottom left corner shows the total RFari, and the bottom right corner shows the forcing due to the effect of BC on surface albedo. Units are Wm^{-2}. Values above the RF panels represent the global mean RF. Values above the standard deviation panels show the standard deviation across the model means, with the global mean of standard deviations across gridboxes in parentheses.

13.3.5.1 Sulfate

Sulfate particles form through oxidation of SO_2 by OH in the gas phase and in the aqueous phase by a number of pathways, including in particular those involving ozone and H_2O_2. The main source of anthropogenic sulfate is from coal-fired power plants, and global trends in anthropogenic SO_2 emissions are estimated to have increased dramatically during the 20th and early 21st centuries (Lamarque et al., 2013). Many developed countries have recently implemented more stringent air pollution controls that have reversed such trends (Klimont et al., 2013; Smith et al., 2011), leading to cleaner air [e.g., (Keene et al., 2014; Ruckstuhl et al., 2008)].

Sulfate particles are highly reflective. On a global scale, the IPCC AR5 estimates that sulfate contributes more than other PM types to RF, with RFari of −0.4 (−0.6 to −0.2) Wm^{-2}, where the numbers in parentheses represent the 5% to 95% uncertainty range (Myhre, 2013). This range indicates the challenges of estimating both SO_2 sources in developing regions and the lifetime of sulfate against wet deposition. Other, more recent estimates are broadly consistent with the AR5 value. Heald et al. (2014) calculated a global RFari of −0.36 Wm^{-2}, while Zelinka et al. (2014) reported an average ERFari value of −0.52 Wm^{-2} across an ensemble of nine CMIP5 models. Sulfate is also a major contributor to the influence of PM on clouds (Takemura, 2012). In their multimodel study, Zelinka et al. (2014) estimated a total effective radiative forcing (ERFari+aci) from anthropogenic sulfate of nearly −1.0 Wm^{-2}.

13.3.5.2 Nitrate

Nitrate particles form through the oxidation of nitrogen oxides, and occur mainly in the form of ammonium nitrate. Ammonium, however, preferentially associates with sulfate rather than nitrate, leading to formation of ammonium sulfate at the expense of ammonium nitrate (Adams et al., 2001). As anthropogenic SO_2 emissions decline in response to air quality control programs, more ammonium will likely become available to react with nitrate, potentially leading to increases in this PM type (Hauglustaine et al., 2014; Shindell et al., 2013). On the other hand, a warming climate may decrease nitrate abundance, as this PM species is highly volatile at warmer temperatures (Tai et al., 2010). Like sulfate, nitrate particles are reflective. The IPCC AR5 estimates a present-day RFari of nitrate of −0.11 (−0.3 to −0.03) Wm^{-2}, approximately one-fourth of the effect of sulfate (Boucher, 2013). By the mid−21st century, however, as SO_2 emissions decline, ammonium nitrate may account for half the total PM global cooling effect (Bellouin et al., 2011).

13.3.5.3 Organic Carbon, Including Brown Carbon

Primary organic particles arise from wildfires, agricultural fires, and from biofuel or fossil fuel combustion. SOA, as mentioned above, forms when anthropogenic or biogenic nonmethane hydrocarbons are oxidized in the atmosphere, leading to less volatile products that may partition into PM [e.g., (Donahue et al., 2012; Jimenez et al., 2009)]. Organic particles are mostly reflective, but in the case of BrC, a portion is significantly absorbing at shorter wavelengths (<400 nm). BrC particles occur most frequently in smoke plumes and in urban areas in the developing world that depend on coal or biofuel for domestic heating (Liu et al., 2014; Feng et al., 2013; Arola et al., 2011).

The IPCC AR5 estimates an RFari for primary organic PM from fossil fuel combustion and biofuel use of −0.09 (−0.16 to −0.03) Wm^{-2} (Myhre, 2013). The RFari estimate for SOA from these sources is −0.03 (−0.27 to +0.20) Wm^{-2}. The wide range of both these RFari estimates, with even the sign of the forcing not consistent across models, reflects uncertainties in both the optical properties of organic

PM and its atmospheric budgets, including the production pathways of anthropogenic SOA (Scott et al., 2014; Myhre et al., 2013; McNeill et al., 2012; Heald et al., 2010).

Trends in biogenic SOA may also have contributed to RFari. Recent work suggests that the expansion of global cropland since the preindustrial era has reduced emissions of biogenic species, resulting in a global mean warming of +0.09 Wm^{-2} due to a diminished concentration of SOA (Unger, 2014). For primary organic PM arising from biomass burning, the IPCC AR5 estimates an RFari of −0.2 Wm^{-2} (Boucher, 2013). Consideration of absorbing BrC may reduce that cooling by as much as 16−25% (Hammer et al., 2016; Lu et al., 2015). When deposited on snow or ice surfaces, BrC, like BC, may contribute to surface warming through the albedo effect, but this forcing has not been quantified.

Of the two types of organic particles—primary versus secondary—primary particles are more effective per unit mass in serving as cloud condensation nuclei (Trivitayanurak and Adams, 2014). Primary organic particles contribute both mass and number concentration in the size range needed to nucleate cloud droplets; they also contribute to the concentration of nanoparticles, which can subsequently grow to the appropriate size. Secondary organic particles (i.e., SOA) condense onto existing particles, which may fall outside the size range of cloud condensation nuclei; in addition, a large amount of SOA forms on particles that already act as cloud condensation nuclei, thereby not affecting the total number of nuclei available.

13.3.5.4 Black Carbon

BC particles occur as a result of inefficient combustion of carbon-containing fuels. Like primary organic PM, BC is emitted by biofuel and fossil fuel combustion and by biomass burning. BC is absorbing at all wavelengths and likely has a large impact on the Earth's energy budget (Bond et al., 2013). The IPCC AR5 estimates a BC RFari from anthropogenic fossil fuel and biofuel use of +0.4 (+0.05 to +0.8) Wm^{-2} (Myhre, 2013). Biomass burning contributes an additional +0.2 (+0.03 to +0.4) Wm^{-2} to BC RFari. The albedo effect of BC on snow and ice surfaces adds another +0.04 (+0.02 to +0.09) Wm^{-2} (Myhre, 2013) (see also Section 13.3.4.4 above).

BC forcing estimates are especially sensitive to the assumptions made about the mixing state of PM (Jacobson, 2012). In an external mixture, different PM types coexist, and each particle consists of a single species. In an internal mixture, each particle consists of a mixture of species. Such a mixture may be homogeneous, or it may occur as a core particle of one species coated with layers of one or more other species. Laboratory and field measurements suggest that BC particles acquire organic coatings as they age in the atmosphere, with subsequent increases in absorption of shortwave radiation (Cappa et al., 2012). These increases likely arise due to enhancement of absorption cross section as the particles grow in size. In addition, the coatings may act as a lens, focusing sunlight onto the BC core, thereby increasing absorption (Klingmueller et al., 2014). Knowledge of the photochemical aging of BC is poor.

As implied above, a large uncertainty in BC forcing involves the magnitude of emissions from biomass burning, which includes wildfire and other forms of open burning. BC is coemitted with OC by biomass burning, and the IPCC central estimate for the total 1750−2011 forcing from biomass burning is in fact zero (+0.2 Wm^{-2} BC forcing and −0.2 Wm^{-2} OC forcing). In the AeroCom ensemble, the total forcing from biomass burning varies in both magnitude and sign across models (Myhre et al., 2013). New field research suggests that biomass burning BC can form large superaggregates in plumes downwind, and that such particles would contribute nearly double the warming per unit optical depth typically assumed for smoke PM in models (Chakrabarty et al., 2014). In one recent study, however, Sena and Artaxo (2015) used satellite data to quantify TOA forcings due to biomass burning smoke during the dry season in Amazonia. They found an overall cooling effect of −5.2 ± 2.6 Wm^{-2}, averaged over 10 seasons.

13.3.5.5 Dust

Dust, also known as mineral dust, has traditionally been classified as scattering. A recent study, however, found that observed dust may be substantially coarser (and thus more light-absorbing) than currently represented in climate models (Kok et al., 2017). Dust mobilization occurs from dry or disturbed soils, and so is linked to both meteorological conditions and human activity, with anthropogenic sources making up about 25% of the total (Ginoux et al., 2012). Through analysis of lake sediment, Neff et al. (2008) determined that the expansion of livestock grazing likely increased dust deposition in the West by a factor of five since the 19th century. Once airborne, dust can strongly attenuate incoming solar radiation (Kavouras et al., 2009; Fairlie et al., 2007). If deposited on snow, dust may accelerate snow melt since dust is darker than snow and may decrease surface albedo (Painter et al., 2012; Skiles et al., 2012). Estimates of global RF related to the change in dust presence since the preindustrial era vary widely due to lack of knowledge both of dust trends (Mahowald et al., 2010) and of dust optical properties (Li et al., 2015). The IPCC AR5 estimates RFari due to dust change since 1750 as −0.1 ± 0.2 Wm^{-2} (Boucher, 2013). The Kok et al. (2017) result, however, suggests that the anthropogenic change in dust may have led to warming, not cooling. Dust may also influence cirrus cloud cover by serving as efficient ice nuclei, although quantifying the resulting forcing is challenging (Kuebbeler et al., 2014; Nenes et al., 2014).

13.3.6 Climate Response to Changing PM, Including Feedbacks

The radiative forcing due to PM elicits a number of responses in the climate system that can lead to significant effects on weather and climate over a wide range of space and time scales, mediated by a number of feedbacks that link PM and climate. For the purposes of this ISA, we focus primarily on climate impacts in the U.S., described in the following section (Section 13.3.7). Here we briefly summarize the mechanisms of climate responses and feedbacks to PM radiative forcing.

In contrast to long-lived greenhouse gases that are well-mixed in the atmosphere, PM has a very heterogeneous distribution across the Earth. The patterns of RFaci and RFari thus tend to correlate with PM loading, with the greatest forcings centered over continental regions (e.g., Figure 13-27). The climate response is more complicated, however, since the perturbation to one climate variable, such as temperature, cloud cover, or precipitation, typically leads to a cascade of effects on other variables. As a result, while the initial PM radiative forcing may be concentrated regionally, the eventual climate response can be spatially much broader (even, ultimately, global) or concentrated in remote regions. For example, increases in absorbing PM over Asia may induce shifts in atmospheric circulation patterns that may, in turn, affect U.S. regional climate (Teng et al., 2012). Because of the complexity of the potential climate system interactions, the spatial relationships between patterns of PM forcing and those of climate response vary greatly among models, with some studies showing relatively close correlation between forcing and surface temperature response [e.g., (Leibensperger et al., 2012a)] and other studies showing much less correlation [e.g., (Levy et al., 2013)].

These climate system responses themselves lead to feedbacks that in turn affect PM. Such PM-climate feedbacks involve a perturbation of regional climate by PM radiative forcing, which in turn leads to meteorologically driven changes in PM emissions, formation, or lifetime. A positive feedback increases PM concentration and amplifies the PM effect on climate, while a negative feedback decreases PM concentration and weakens the PM effect on climate. Examples of such feedbacks occurring on the regional scale include those involving wildfires, inversions, clouds, and convection, PM-albedo effects, and biogenic emissions.

For example, wildfires are expected to increase in a warming world [(Yue et al., 2013; Pechony and Shindell, 2010)], and agricultural fires may also increase as more land is cleared for crops and timber plantations, particularly in the tropics (Margono et al., 2012). Smoke from these fires contain a mix of absorbing (BC and BrC) and scattering particles and so may affect the climate in complex ways. In their model study, Tosca et al. (2010) found that smoke from fires reduced solar radiation at the surface by 1.3 Wm^{-2}, corresponding to a global mean temperature decrease of $-0.13 \pm 1°C$. Absorption of solar radiation by smoke particles warmed the troposphere, and that warming, together with the cooler surface temperatures, weakened the Hadley circulation and decreased precipitation over tropical forests. Such a positive feedback would further enhance fire activity in the tropics.

Another example of PM-climate feedback involves atmospheric inversions, especially over mountain basins. Such inversions limit ventilation and promote accumulation of surface PM; and the enhanced PM can further intensify the inversion. For example, over Salt Lake City in Utah, haze episodes during wintertime inversion events diminish the penetration of solar radiation and cool the surface further, strengthening the inversion and exacerbating the haze (Lareau et al., 2013). In their modeling study, Jacobson and Streets (2009) found a similar positive feedback of PM on pollution levels in Los Angeles: atmospheric stability over Los Angeles was enhanced by a combination of warming of the air by BC and

cooling of the ground by all particle types, including BC. The resulting decrease in precipitation lengthened the lifetime of PM in that study.

Invoking similar mechanisms, Cook et al. (2009) identified atmospheric dust as a probable amplifier of the Dust Bowl drought of the 1930s. The drought, together with the agricultural practices prevalent in that era, likely resulted in the mobilization of a massive amount of dust, which would, in turn, have warmed the local atmosphere, suppressing convection and exacerbating drought conditions [see also (Xing et al., 2016)]. In contrast, Zhang et al. (2010) calculated that heating by BC particles may invigorate convection under certain conditions, thereby increasing surface ventilation and precipitation. More recently, Mashayekhi and Sloan (2014) calculated a 15% decrease in convective precipitation due to PM radiative effects in the northeastern U.S., but a 30% increase in large-scale precipitation in this region due to the influence of PM on clouds.

As described in Section 13.3.3.3, deposition of BC and other absorbing species on Arctic snow and sea ice may decrease surface albedo and accelerate warming at high latitudes (Bond et al., 2013; Lee et al., 2013; Skeie et al., 2011; Flanner et al., 2007). Model studies have suggested that this rapid warming could shift the polar jet northward, decreasing cold front frequency over mid-latitudes and lengthening stagnation episodes (Turner et al., 2013; Leibensperger et al., 2008). An increase in stagnation would likely intensify pollutant events in source regions. Transport of pollution to the Arctic could also be affected, but this feedback onto Arctic BC deposition has not been studied.

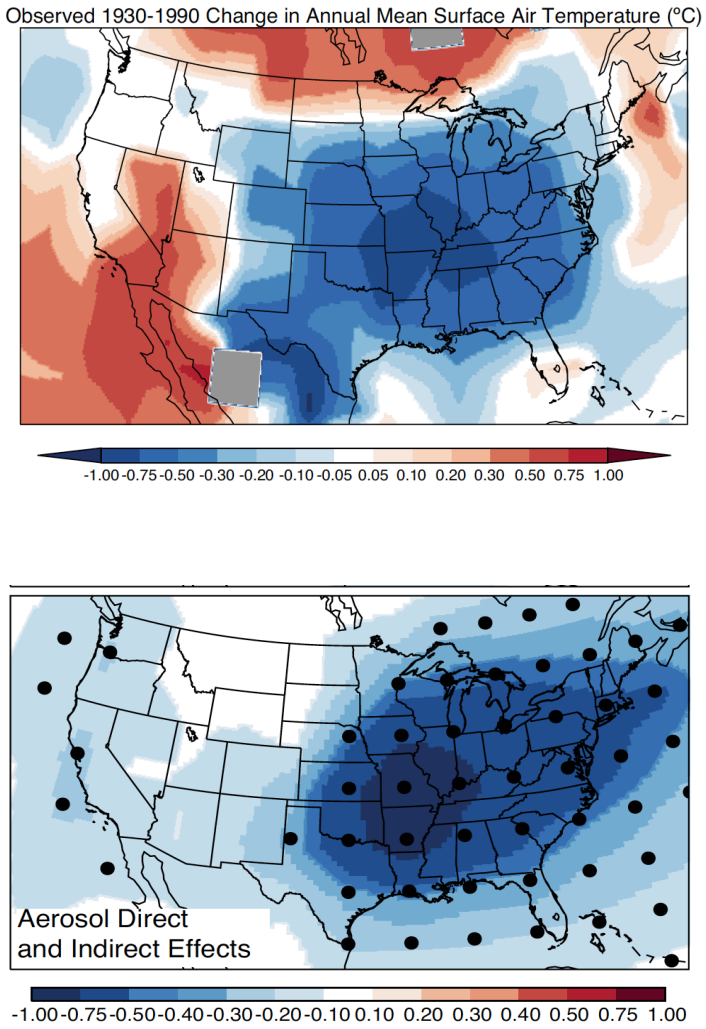
A final example involves biogenic SOA, which arises from the complex oxidation pathways of biogenic species such as isoprene and monoterpenes. As biogenic emissions are strongly temperature-dependent, SOA concentrations are expected to increase in a warming climate (Wu et al., 2012; Heald et al., 2008), even if the so-called "CO_2 inhibition effect" is taken into account (Tai et al., 2013). Such regional increases in reflective PM could significantly cool the underlying surface, thereby limiting the magnitude of SOA enhancement (Arneth et al., 2010).

13.3.7 Effect of PM on U.S. Regional Climate

The effects of PM on U.S. regional climate have been examined on several different spatial and temporal scales. Some studies have investigated the impact of PM on urban microclimates [e.g., (Jacobson et al., 2007)]. Other studies have diagnosed weekly cycles in temperature or precipitation, which taken together suggest that weekly variations in anthropogenic PM may influence regional weather patterns [e.g., (Bell et al., 2008; Forster and Solomon, 2003)]. A key question, however, is to what extent PM trends in the U.S. may have partially offset the warming effects of rising greenhouse gases over the course of the 20th century.

Over the contiguous U.S., surface temperatures warmed during the early decades of the 20th century, remained relatively flat from about 1960 to 1980, then rose rapidly by ~1°C from 1980 to 2010

(NAS, 2014). A closer look at spatial trends in these temperatures reveals a strong cooling trend of approximately −1°C from 1930 to 1990 in the Southeast, centered over Arkansas and Oklahoma (Leibensperger et al., 2012a) (Figure 13-28). Mascioli et al. (2017) pointed out that between 1950 and 2000 the cooling extended over much of the eastern U.S. This observed cooling, which took place even as much of the globe warmed in response to greenhouse gases, is sometimes referred to as the U.S. "warming hole" (Pan, 2004). Several studies have linked the U.S. warming hole to natural variability [e.g., (Banerjee et al., 2017)], in particular to decadal variation in North Atlantic or Pacific sea surface temperatures (SSTs) (Meehl et al., 2015; Kumar et al., 2012; Meehl et al., 2012; Kunkel et al., 2006). Such variability can influence large-scale meteorological processes, which in turn may affect temperatures in continental interiors such as the central or south-central U.S. In one multimodel study, those models that best represented the Atlantic Multidecadal Oscillation also best reproduced the warming hole, although even those models showed large discrepancies with observations (Kumar et al., 2012).



Top: Temperature change is based on a linear trend, and observations are from the NASA GISS Surface Temperature Analysis (GISTEMP, http://data.giss.nasa.gov/gistemp/).

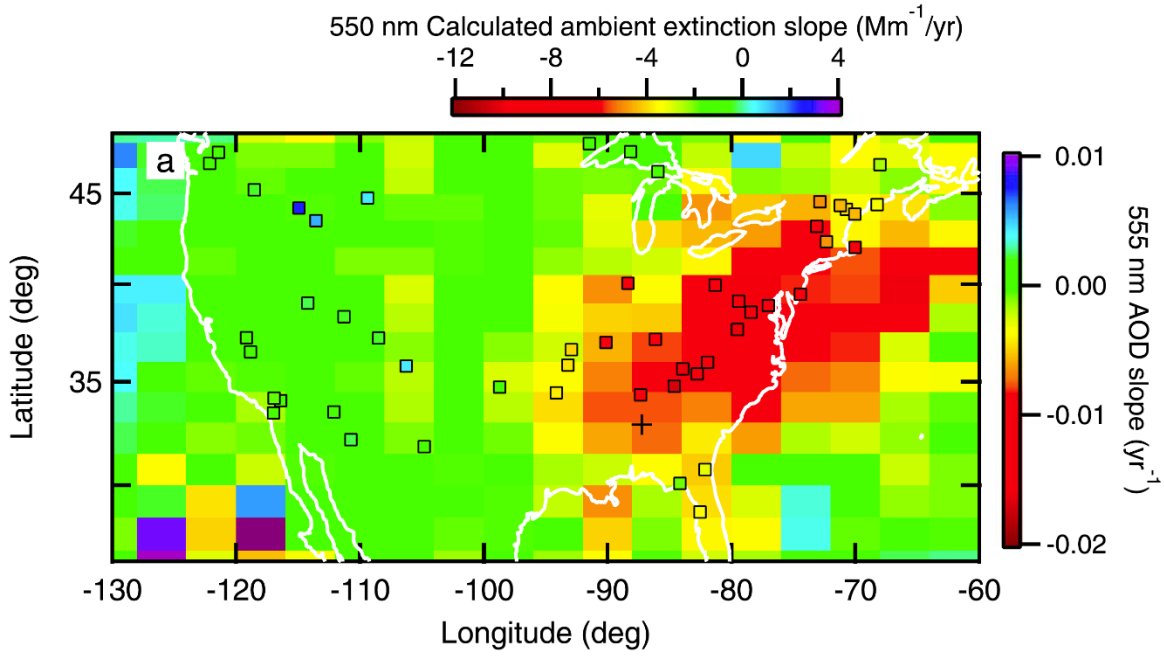
Bottom: Units are °C. Values represent the mean difference between two sets of 5-member ensemble simulations in a climate model; one set includes U.S. anthropogenic PM sources and one does not. Interactions of PM with both radiation and clouds are considered. Dots indicate differences significant at the 95th percentile.

Source: Permission pending, Leibensperger et al. (2012a).

Figure 13-28 Top: Observed change in surface air temperatures between 1930 and 1990. Bottom: Effect of U.S. anthropogenic PM sources on surface air temperatures for the 1970−1990 period when U.S. particulate loading was at its peak.

Other studies have suggested that trends in PM loading may be partly responsible for the unusual cooling trend in the southeastern U.S. during the mid-20th century (Section 13.3.2.1). PM in the Southeast is dominated by a mix of sulfate and organic species. In recent years, PM levels in this region have declined in response to emissions controls, possibly contributing to the observed increase in solar

radiation at the surface. For example, from 2001 to 2013, observed AOD across the Southeast decreased an average −4% per year (Figure 13-29), while surface solar radiation in the region increased by +8 Wm^{-2} (Attwood et al., 2014). Gan et al. (2014), however, reported increases in both direct and diffuse surface solar radiation, at least averaged over the whole of the eastern U.S. from 1995 to 2010. The results of Gan et al. (2014) are difficult to interpret due to the seeming discrepancy between a decrease in PM and an increase in diffuse radiation. Additionally, it is unclear why the greatest cooling occurred in the relatively rural Southeast, away from the historically large sources of anthropogenic PM such as power plants in the Ohio River Valley. As discussed above, climate responses to PM radiative forcing can be nonlocal, but it is not clear what may have caused this particular mismatch in forcing and climate response.



Note: The open squares denote trends in ambient extinction, a measure of how much solar radiation reaches the Earth's surface, from the IMPROVE network. The plus symbol indicates the site of the 2013 Southern Oxidant and Aerosol study, which analyzed aerosol extinction as a function of relative humidity.

Source: Permission pending, Attwood et al. (2014).

Figure 13-29 Trends in aerosol optical depth (AOD) measured by the Multi-angle Imaging SpectroRadiometer (MISR) satellite instrument over the 2001−2013 time period.

To address these issues, several model studies have tried to recreate the observed trends in AOD, surface radiation, and surface temperatures. Leibensperger et al. (2012a, 2012b) found that the regional RF from anthropogenic PM elicits a strong regional climate response, cooling the central and eastern U.S.

by 0.5−1.0°C on average during 1970−1990, with the strongest effects on maximum daytime temperatures in summer and autumn (Figure 13-28). In this study, the spatial mismatch between maximum PM loading and maximum cooling could be partly explained by the outflow of PM cooling the North Atlantic, which then strengthens the Bermuda High in the model and increases the flow of moist air into the south-central U.S. Local feedback effects involving soil moisture and cloud cover may also amplify the surface temperature response to changing PM loading in the Southeast (Mickley et al., 2012; Liang et al., 2005; Pan, 2004).

The Leibensperger et al. (2012a, 2012b) studies suggest that the influence of PM on radiation and clouds plays a significant role in driving regional cooling in the Southeast. In contrast, a more recent model study, Yu et al. (2014) determined that the U.S. warming hole can best be explained by the PM interactions with clouds alone. Meanwhile, Attwood et al. (2014) attributed 20% of the observed increase in surface solar radiation in the Southeast to a decrease in the sulfate/organic ratio of PM. As sulfate is more hygroscopic than organic material, a decline in sulfate would decrease particle water content and thus particle extinction, leading to local brightening—i.e., more sunlight reaching the surface. In contrast to Yu et al. (2014), the Attwood et al. (2014) result implies that at least some of the warming hole can be attributed to aerosol-radiation interactions. More recently, Mascioli et al. (2017) used an ensemble of observations and IPCC model simulations to conclude that both PM and natural variability contributed to the U.S. warming hole, at least in summer.

Overall, therefore, several lines of evidence suggest an important influence of PM on observed 20th century temperature trends over the southern and eastern U.S. A number of key uncertainties, however, mean that alternative explanations cannot be ruled out at this time, and further research is needed.

13.3.8 Uncertainties in Estimates of PM Effects on Radiative Forcing and Climate: Summary

In general, uncertainties associated with clouds and aerosols continue to be the largest contributors to overall uncertainty in evaluating climate change trends and projecting future climate changes (Boucher, 2013). With respect to PM-climate uncertainties specifically, there has been significant progress since the 2009 ISA. According to the IPCC AR5, "Climate-relevant aerosol processes are better understood, and climate-relevant aerosol properties better observed, than at the time of AR4" (Boucher, 2013). Nevertheless, significant uncertainties still remain which make it difficult to precisely quantify the climate effects of PM. This is because the properties of PM, and those of the clouds with which PM interacts, vary substantially on scales much smaller than those able to be represented in even the most recent generation of climate models. In addition, as described above, the initial radiative forcing effect of PM leads to a diverse range of regionally heterogeneous climate impacts associated with changes in the hydrologic cycle and atmospheric circulation patterns, mediated by a variety of feedbacks, and interacting

in complex ways with other forced and natural sources of climate variability and change occurring simultaneously. This makes it difficult to characterize the total net impact of PM on climate and to disentangle the unique contribution of PM to overall climate change.

As discussed throughout this section, uncertainties in estimates of PM effects on climate arise from many sources. First, there is a lack of knowledge of PM abundance. Unlike the well-mixed greenhouse gases, PM is not uniformly distributed through the atmosphere and the current spatial distribution of PM concentrations is not well quantified (Myhre, 2013). Long-term measurements of PM are rare and mainly surface-based, making it challenging to estimate trends in AOD, which are key to estimating climate impacts (Koch et al., 2011). In particular, calculation of the RF of anthropogenic PM requires precise knowledge of preindustrial particle load; this is especially true for determining RFaci (Carslaw et al., 2013). Measurements from ice cores and lake-core sediments offer the only constraints on PM of the preindustrial era; such sparse measurements cannot capture the spatial distribution of this era. Another difficulty in estimating the climate impacts of anthropogenic PM lies in quantifying the contribution of natural PM to observed trends (Heald et al., 2014). The production and loss rates of natural PM depend on meteorological variables such as temperature, and so change with changing climate. The sensitivity of these rates to meteorology is not well characterized.

Anthropogenic emissions of PM or their precursors are also not well constrained in models (Boucher, 2013), but even application of the same emission inventories to an ensemble of climate models yields a large range of PM concentrations (Shindell et al., 2013). Some of the discrepancies among models likely arise from uncertainties in the oxidation pathways leading to PM production or in PM lifetime against wet deposition (Achakulwisut et al., 2015; Wang et al., 2011b). Discrepancies in RF estimates of PM arise in part from uncertainties in the optical properties of particles. Particle size, complex refractive index, shape, and lifetime are functions of particle water content, and these properties all influence the magnitude of PM RF. Finally, the microphysics of the effects of PM on clouds are not well represented in coarse-grid climate models (Trivitayanurak and Adams, 2014; Boucher, 2013). Some processes driving the interactions between PM and clouds are relatively well understood (e.g., cloud droplet activation), while scientific knowledge of other processes is lacking (e.g., ice nucleation) (Rosenfeld et al., 2014). Both kinds of processes are challenging to translate into macroscale processes such as large-scale precipitation or radiative fluxes (Rosenfeld et al., 2014). Better knowledge of the number and size distributions of emitted particles, including nanoparticles from vehicle exhaust, is also needed to constrain PM-cloud interactions (Adams et al., 2013).

As discussed in the previous subsection, several model studies point to the possibly large influence of changing sulfate on regional surface temperatures in the southeastern U.S. However, reconciling the observed increase in diffuse radiation at some sites with decreasing PM load is challenging (Gan et al., 2014). Another uncertainty in studies of the PM effects on U.S. regional climate involves biogenic SOA. The gas/particle partitioning of organic material depends in part on ambient PM concentrations, with more SOA formed in the presence of sulfate PM (Weber et al., 2007; Donahue et al.,

2006). Recent model studies have attempted to determine to what extent trends in anthropogenic PM in recent decades may have also influenced biogenic SOA formation (Marais et al., 2017; Carlton et al., 2010) and thus surface cooling. The uncertainties in such studies, however, are large.

More indirectly, there is a growing body of evidence that aerosol forcing may drive shifts in internal modes of long-term (e.g., multidecadal) climate variability in the North Atlantic (Zhang et al., 2013a; Booth et al., 2012; Evan et al., 2009), in turn can potentially affecting regional temperature and rainfall patterns in North America, as well as Atlantic tropical storms (Dunstone et al., 2013).

Finally, while trends in PM may affect climate at the regional scale, global climate change may, in turn, influence PM abundance. For example, climate-driven changes in monsoon strength will almost certainly affect PM abundance over Asia (Turner and Annamalai, 2012), while increasing warming surface temperatures over the western U.S. may enhance wildfire PM (Yue et al., 2014; Yue et al., 2013). Absent future changes in land use, the concentration of biogenic SOA will likely increase in response to warming temperatures and greater isoprene emissions over the 21st century (Shen et al., 2017; Tai et al., 2013), though declines in anthropogenic emissions have the potential to at least partially counteract this effect (Carlton et al., 2010). Observations also reveal a strong positive dependence of sulfate PM to temperature in the eastern U.S., which could likewise have implications in the future warmer climate (Shen et al., 2017). Disentangling these different effects on PM abundance—the influence of global climate change versus feedbacks from the regional climate response to changing PM—remains challenging and continues to be the subject of active research.

13.3.9 Summary and Causality Determination

The 2009 ISA concluded that there was sufficient evidence that a causal relationship exists between PM and climate effects—specifically on the radiative forcing of the climate system, including both direct effects of PM on radiative forcing and indirect effects involving cloud processes. Recent research reinforces and strengthens the evidence evaluated in the 2009 PM ISA. New evidence provides greater specificity about the details of these radiative forcing effects and increased understanding of additional climate impacts driven by PM radiative effects. This section describes the evaluation of evidence for climate effects, with respect to the causality determination, using the framework described in Table II of the Preamble to the ISAs (U.S. EPA, 2015).

The scientific consensus is that anthropogenic PM has generally cooled the atmosphere over the 20th and early 21st century, masking some of the effects of greenhouse gas warming (Myhre, 2013). In response to health concerns, PM concentrations have begun declining in many developed nations [e.g., (De Meij et al., 2012)], a trend that can be observed from space (Jongeward et al., 2016). Such declines likely contributed to the current trend in global "brightening," which follows a decades-long period of global "dimming" (Wild, 2009). The brightening, in turn, may have led to rapid warming in North America and Europe, as greenhouse-gas warming was unmasked (Turnock et al., 2015;

Leibensperger et al., 2012a, b; Philipona et al., 2009; Ruckstuhl et al., 2008). In contrast, PM concentrations have increased in recent decades over developing countries in much of Asia (Jongeward et al., 2016; Shindell et al., 2013). The sign of recent RF over developing countries, however, is very uncertain due to lack of accurate information on emissions and the relative abundances of reflecting species versus absorbing species. Research since the 2009 PM ISA has also improved characterization of the key sources of uncertainty in estimating PM climate effects, particularly with respect to PM-cloud interactions. The IPCC AR5 states that "Climate-relevant aerosol processes are better understood, and climate-relevant aerosol properties better observed, than at the time of AR4" (Boucher, 2013). Substantial uncertainties, however, still remain with respect to key processes linking PM and climate, both because of the small scale of PM-relevant cloud microphysical processes compared to the resolution of state-of-the-art models, and because of the complex cascade of indirect impacts and feedbacks in the climate system that result from a given initial radiative perturbation caused by PM. These uncertainties continue to limit the precision with which these effects can be quantified. **Despite these remaining uncertainties, though, overall the evidence is sufficient to conclude that a causal relationship exists between PM and climate effects.**

13.4 Effects on Materials

13.4.1 Introduction

The 2009 PM ISA (U.S. EPA, 2009) concluded a causal relationship between PM and effects on materials, noting that building materials including metals, stone, cement, and paint undergo natural weathering processes that are enhanced by exposure to anthropogenic pollutants. Effects of PM deposition to materials include both physical damage and impaired aesthetic qualities. It was concluded that particulate deposition can result in increased cleaning frequency and reduced usefulness of soiled material, and that although attempts had been made to quantify pollutant exposure corresponding to perceived soiling and damage, insufficient data were available to improve understanding of perception thresholds with respect to pollutant concentration, particle size, and chemical composition.

The two major processes by which air pollution in general and PM in particular can bring about materials damage are soiling and corrosion. Soiling has been defined generally as "a visual nuisance resulting from the darkening of exposed surfaces by deposition of atmospheric particles" (Lombardo et al., 2005) and more precisely as "a surface degradation that can be undone by cleaning," and the physical measure of soiling has been defined as "the contrast in reflectance of particles on a substrate to the reflectance of the bare substrate," definitions that remain widely used (Watt et al., 2008; Saiz-Jimenez, 2004; Haynie, 1986a). Corrosion is a chemical attack of a material surface that degrades a material surface and decreases aesthetic value and mechanical strength (Watt et al., 2016) (Watt et al., 2008), and in ambient air it typically involves reactions of acidic PM (i.e., acidic sulfate or nitrate) with material

surfaces, but gases like SO_2 and HNO_3 also contribute to atmospheric corrosion, and recent research on materials damage by both gaseous and particulate oxides of nitrogen and sulfur will also be considered in this section.

The increased cleaning, washing, and repainting of solid surfaces create a major economic cost and reduces the useful life of soiled material. Long-term effects of soiling are primarily from fine rather than coarse particles, as coarse particles are relatively easily removed by wind and rain (Creighton et al., 1990; Haynie and Lemmons, 1990). As reviewed in the 2009 PM ISA (U.S. EPA, 2009), soiling is dependent on atmospheric particle concentration, particle size distribution, deposition rate, and the horizontal or vertical orientation and texture of the exposed surface (Haynie, 1986b). The chemical composition and morphology of the particles and the optical properties of the surface being soiled will determine the time at which soiling is perceived by human observers (Nazaroff and Cass, 1991). Since the 2009 PM ISA (U.S. EPA, 2009), additional research has enabled further characterization of PM effects on materials, although uncertainties remain such as quantitative relationships between particle concentration and frequency of repair, deposition rates of airborne PM to surfaces, and the interaction of copollutants in regard to materials damage effects. There is new information on the soiling process, types of materials, such as glass, and dose-response and damage functions described below. Most of the recent work on this topic has been conducted outside of the U.S. on buildings and other items of cultural heritage.

13.4.2 Soiling and Corrosion

Soiling and corrosion are complex, interdependent processes, typically beginning with deposition of atmospheric PM to exposed surfaces. Constituents of deposited PM can interact directly with materials or undergo further chemical and/or physical transformation to cause soiling, corrosion, and physical damage. Weathering, including exposure to moisture, ultraviolet (UV) radiation and temperature fluctuations affects rate and degree of damage.

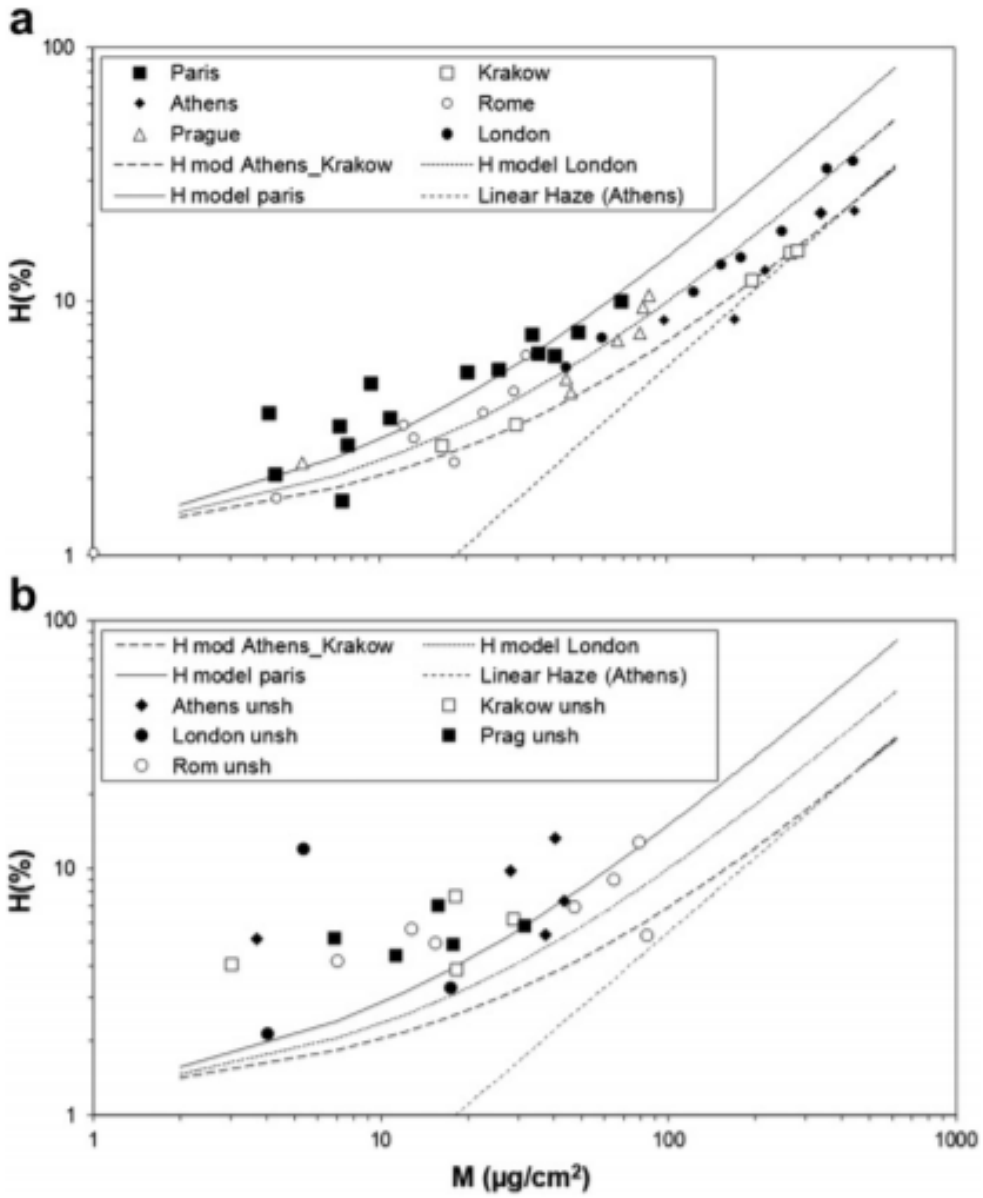
Deposition of SO_2 to materials such as limestone ($CaCO_3$), granite, and metal intensifies soiling. Deposited SO_2 is oxidized to sulfate, in the case of limestone ($CaCO_3$), transforming it into gypsum ($CaSO_4$). As gypsum forms, the surface becomes rougher, further increasing PM deposition (Camuffo and Bernardi, 1993). Organic and elemental carbon from deposited PM both contribute substantially to black crusts (Bonazza et al., 2005; Sabbioni et al., 2003). This not only enhances soiling because of carbonaceous PM, but the deposited PM also forms coatings, creating ideal conditions for more rapid SO_2 oxidation catalyzed by carbon and metals present in the deposited PM (McAlister et al., 2008; Grossi et al., 2007).

Research has progressed on theoretical understanding of soiling of cultural heritage since the 2009 PM ISA (U.S. EPA, 2009). Trace element concentrations were measured and heavy metals were detected in black crusts on stone monuments (Barca et al., 2010), and the nature, causes, and mitigation strategies for decay of stone-built heritage have been reviewed (Smith et al., 2008). Isotope tracers have

also been applied to understand the origin of contaminant sources in black crusts (Kloppmann et al., 2011). Biological marker compounds indicating the presence of biogenically derived material confirmed that biological activity played a major role in producing black films on granite (de Oliveira et al., 2011). Indoor penetration and accumulation of PM and gaseous pollutants into historical buildings was also studied (Worobiec et al., 2010).

There has also been considerable progress understanding soiling of materials besides stone. Gypsum was found to be the main damage product in concrete, and organic and elemental carbon were also found in concrete damage layers (Ozga et al., 2011). Gypsum formation was also observed after exposure of rendering mortars to sulfuric acid (Lanzon and Garcia-Ruiz, 2010). A new physically based model was recently developed to predict haze[85] forming on modern glass that takes into account differences in particle size distributions observed in different locations (Alfaro et al., 2012). Results are plotted in Figure 13-30, showing good model fits under sheltered conditions from the rain and haze on the glass reaching a 50% ratio of diffuse transmitted light to direct transmitted light.

[85]In this section (13.4) haze is used as it has been defined in the scientific literature on soiling of glass, i.e., the ratio of diffuse transmitted light to direct transmitted light (Lombardo et al., 2010). This differs from the use of the word haze in Sections 13.2 and Section 13.3, where it is used as a qualitative description of the blockage of sunlight by dust, smoke, and pollution. This usage is widespread in the scientific literature on visibility and in discussion of the Regional Haze Rule. Both definitions are used in this chapter because use of the word haze in discussion of either regional haze and glass soiling is unavoidable.



Source: Permission pending, Alfaro et al. (2012).

Figure 13-30 Increase of haze (H in %) with mass of deposit on glass (M µg/cm^2) under a) sheltered conditions and b) conditions where glass panes were exposed directly to the weather.

Corrosion of stone has been discussed in the 2009 PM ISA, and decay of stone building materials by acid deposition and sulfate salts were described (U.S. EPA, 2009). Advances since the 2009 PM ISA include quantification of degradation rates and further characterization of factors that influence damage of stone materials. Measurable losses of surface material were used to determine decay rates of marble grave stones up to 2.5 to 3.0 mm/century in heavily polluted areas compared to natural background decay rates from a relatively pristine area of 0.25 mm/century (Mooers et al., 2016). Both time of wetness and the number of dissolution/crystallization cycles were identified as hazard indicators for stone materials, with the greatest hazard in spring and fall when both time of wetness and the number of dissolution and crystallization cycles were relatively high (Casati et al., 2015). Improvements of facilities for further research to simulate interactions between cultural heritage materials and realistic atmospheric environments that facilitate controlled experimental conditions in order to investigate various factors influencing decay are also underway (Chabas et al., 2015).

Corrosion of steel as a function of PM composition and size was also recently studied, and changes in composition of resulting rust varied with particle size (Lau et al., 2008). A multipollutant study of damage to metal materials under ambient conditions in severely polluted Hong Kong concluded that iron and steel were corroded more by air pollution than copper and copper alloys, which were in turn more corroded by air pollution than aluminum and aluminum alloys (Liu et al., 2015). SO_2, NO_2, and PM contributed to corrosion of iron and steel, while SO_2 and O_3 were mainly responsible for corrosion of copper and copper alloys, and NO_2 and PM for damage to aluminum and aluminum alloys (Liu et al., 2015).

Other atmospheric gases besides SO_2, and other components of particulate matter besides sulfate and black carbon can damage materials. Nitrates are more soluble than sulfates, and do not form stable compounds with stone building materials (Sabbioni et al., 1998). However, calcium nitrate can be formed by NO_X attack (Haneef et al., 1993). Also, NO_X can enhance sulfate attack on calcium rich building materials, and synergistic effects between NO_2 and SO_2 at high relative humidity have been reported (Johansson et al., 1988). Airborne organic compounds have also been observed on building material surfaces and can participate in damage, (Sanjurjo Sanchez et al., 2009; Sabbioni et al., 1998; Saiz-Jimenez, 1993), serving as nucleation sites for growth of gypsum crystals (Cultrone et al., 2000; Saiz-Jimenez, 1993). In some cases, soiling of limestone and building material surfaces has been attributed to biological processes (Viles and Gorbushina, 2003), and carbonaceous particles and organic compounds also enhance biological colonization (Sanjurjo-Sanchez and Alves, 2012). Black carbon has recently been observed to induce structural, composition, and functional changes in biofilms, to produce thicker and more complex biofilms, and potentially to act as a novel signal to induce biofilm formation (Hussey et al., 2017).

In addition to structural and aesthetic impacts, energy efficiency is also becoming an important consideration for impacts of air pollutants on materials. A growing area of research is the impact of air pollution on the energy yield from photovoltaic panels, especially in desert environments. Results indicate

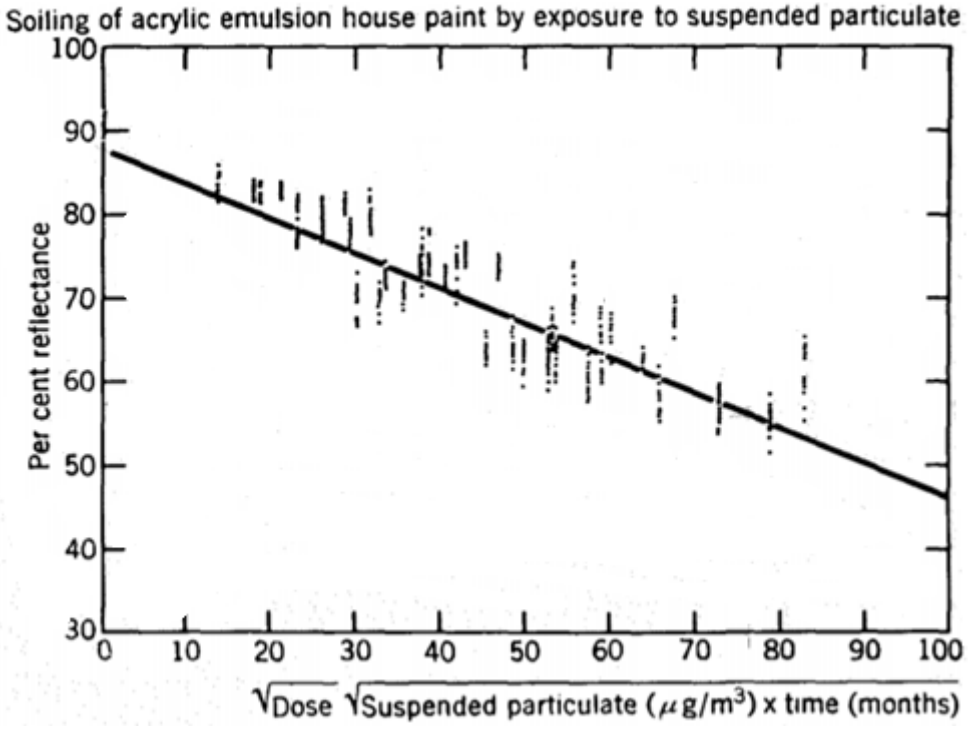
the type of dust deposited and glazing temperature influence light transmission (Abderrezek and Fathi, 2017). For example, on average, carbon soiling decreased solar modular efficiency by 37.6% while soil particles reduced efficiency by 68% and $CaCO_3$ by 37.6% (Radonjic et al., 2017). The relationship between the rate of degradation of photovoltaic power output due to soiling has been investigated and related to dust accumulation rate, and impacts of season and dust storms were observed (Besson et al., 2017; Boyle et al., 2017; Javed et al., 2017). In five sites in the continental U.S. (Cocoa, FL, Albuquerque, NM, and a rural, suburban, and urban location in the Front Range of Colorado) photovoltaic module power transmission was reduced by 2.8% for every g/m^2 of PM deposited on the cover plate independent of geographical location (Boyle et al., 2017). Mean deposition velocities were 1.5 cm/s. In arid environments dust fouling was observed to reduce photovoltaic module power output by 40% after 10 months without cleaning (Walwil et al., 2017). There is on-going research to reduce soiling of photovoltaic cells with transparent coatings (Quan and Zhang, 2017).

The use of materials able to reflect a large portion of solar radiation for passive cooling, such as light-colored marble panels on building exteriors, are another example of an approach to improving energy efficiency, and also to countering the urban heat island effect. Exposure to acidic pollutants in urban environments reduces solar reflectance of marble, decreasing the cooling effect of the marble envelope (Rosso et al., 2016).

13.4.3 Dose-Response Relationships

Typically, empirical models are used to estimate dose-response relationships from field measurements of data relevant to deposition and meteorological processes (Hamilton and Mansfield, 1993). There has been considerable progress since the 2009 PM ISA (U.S. EPA, 2009) in the development of dose-response relationships for soiling of building materials, although some key relationships remain poorly characterized. Dose-response estimates can be traced back to early research on surface repainting, showing a direct correlation between ambient PM concentration and the number of years between repainting (U.S. EPA, 1972). Consistent and reliable dose-response relationships for soiling of stone building materials have proved difficult to estimate, but there is a growing literature of dose-response relationships for newer building materials, such as glass, metals, and polymers.

The first general dose-response relationships for soiling of materials by particles were generated by measuring the contrast in reflectance of a soiled surface to the reflectance of the unsoiled substrate for different materials, including acrylic house paint, cedar siding, concrete, brick, limestone, asphalt shingles, and window glass in different areas with total suspended particulate (TSP) concentrations from 59 to 289 $\mu g/m^3$(Beloin and Haynie, 1975). The dose-response curve for acrylic house paint in Figure 13-31 plots change in reflectance against the square root of the dose, defined as the product of TSP and number of months exposed (Beloin and Haynie, 1975).



Source: Permission pending, Beloin and Haynie (1975).

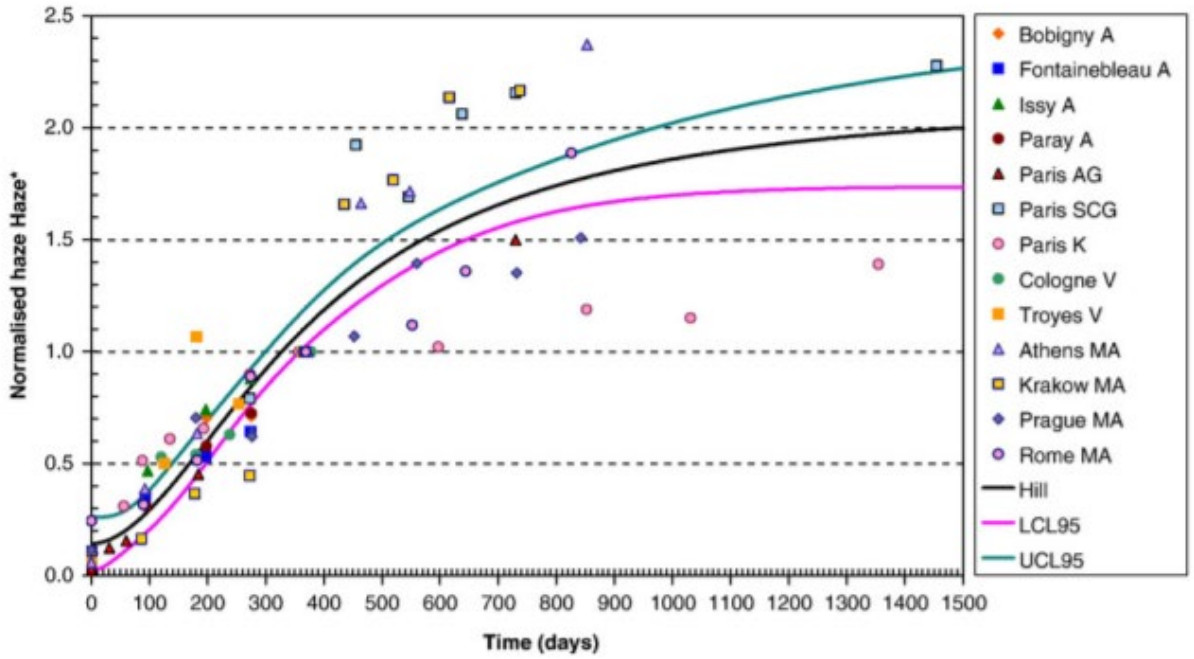
Figure 13-31 Example of a dose-response curve for effects on materials, showing change in reflectance vs. square root of dose for acrylic emulsion house paint.

Efforts to develop accurate dose-response curves similar to those in Figure 13-31 have proved difficult because of multiple influences and considerable scatter in the data for most materials. Continued efforts to develop dose-response curves for soiling have led to some advancements for modern materials, but remain poorly characterized for limestone. PM_{10} measurements and collocated reflectance measurements of material surfaces for limestone, painted steel, white plastic, and polycarbonate filter material were recently used to quantify dose-response relationships between PM_{10} and soiling. In this recent case also, there was too much scatter in the data for limestone to produce a dose-response relationship (Watt et al., 2008). A dose-response relationship for silica-soda-lime window glass soiling by PM_{10}, NO_2, and SO_2 based on 31 different locations was quantified (Lombardo et al., 2010), and described by Equation 13-8:

$$Haze = (0.2529[SO_2] + 0.1080[NO_2] + 0.1473[PM_{10}]) \times \frac{1}{1 + \left(\frac{382}{t}\right)^{1.86}}$$

Equation 13-8

Figure 13-32 shows the raw data on which this dose-response curve was based, illustrating that long observation times of several years required as well as the challenges posed by response differences among locations.



Source: Permission pending, Lombardo et al. (2010).

Figure 13-32 Temporal trend in haze values of glass at different locations. The x-axis is normalized haze values where 1-year data series were combined with longer data series and scaled by the 1-year value. Black line represents a fitted model of the data and pink and green lines represent 95% confidence.

Glass soiling was intensively studied to evaluate deposited PM composition and optical properties including reflectance, transmittance, and absorption in several European cities. After more than two years, there was no saturation phenomenon, i.e., material continued to accumulate through deposition, although disappearance of ammonium and possible particulate organic matter were reported. Absorption and transmittance changed "quasi-linearly" with species concentrations for elemental carbon and major ions

for thin deposits, but for thicker deposits saturation was reached for absorption of 16% when elemental carbon concentrations reached 15 µg/cm^2 and for diffuse transmittance of about 30% for 65 µg/cm^2 of ions, and the overall saturation level for transmittance was dependent of composition and particle size (Favez et al., 2006).

As these studies indicate, for some materials it can sometimes take years to develop dose-response relationships that relate reflectance of materials surfaces to ambient PM concentrations. There has also been progress in developing methods to more rapidly evaluate soiling of different materials by PM mixtures. Modern buildings typically have simpler lines, more limited surface detail, and greater use of glass, tile, and metal that are easier to clean than stone. There have also been major changes in types of materials used for buildings, including a wide variety of polymers available for coatings and sealants. In addition, new economic and environmental considerations beyond aesthetic appeal and structural damage are emerging. For example, cool roofs have been designed and constructed to increase reflectance from buildings in urban areas, to decrease both air conditioning needs and urban heat island effects, and these efforts can be impeded by soiling of materials. Sleiman et al. (2014) developed a reliable and repeatable accelerated aging method for roofing products that simultaneously simulates soiling by urban PM and weathering and can be adjusted to local PM composition.

13.4.4 Damage Functions

Dose-response functions and damage functions have been used to quantify material decay as a function of pollutant type and load. The damage function approach follows a number of steps (ApSimon and Cowell, 1996). First, a dose-response function is determined with dose based on either concentration or deposition. Alternatively, damage can be determined from sample surveys or inspection of actual damage (ApSimon and Cowell, 1996). Second, a physical damage function is developed. This can then be linked to the rate of material damage to time of replacement or maintenance. Finally, a cost function links time for replacement and maintenance to a monetary cost, and an economic function links cost to dose of pollution. Figure 13-33 shows an example of how damage functions are used to assess economic damage and replacement costs (ApSimon and Cowell, 1996; Kucera et al., 1993).

Source: Permission pending, Kucera et al. (1993) as cited by ApSimon and Cowell (1996).

Figure 13-33 Damage functions and their use to determine maintenance and replacement costs for materials damaged by SO_2.

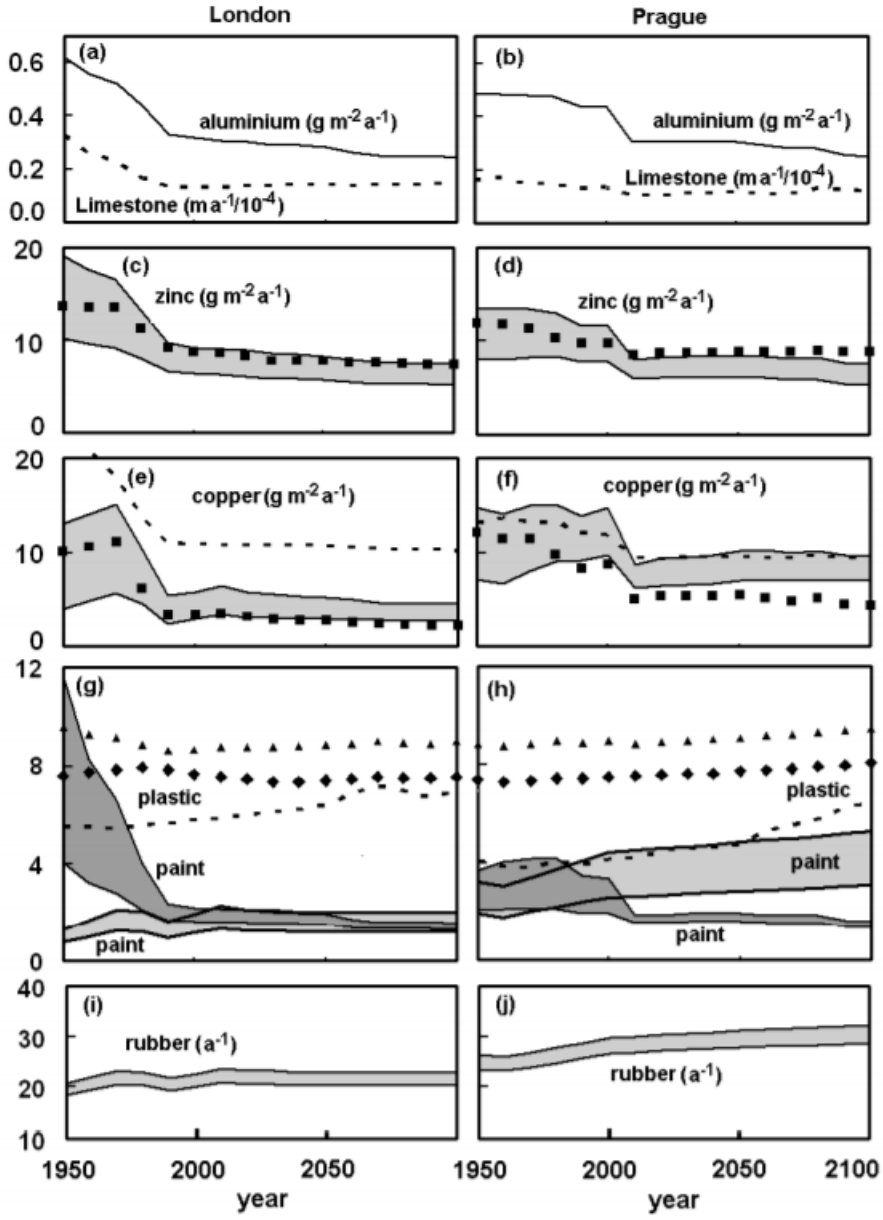
The physical damage function is also difficult to assess because it depends on human perception of the level of soiling to be tolerated. Damage functions based on steady state loss mechanism for erosion have been calculated but did not account for effects of black crusts (Lipfert, 1989). An example of a damage function from Lipfert (1989) is given by Equation 13-9, expressing the loss of calcerous stone in mm thickness as a result of wet deposition of SO_2 in rain with pH of 3−5:

$$Loss/_{m\ rain} = 18.8 + (0.016)H^+ + (0.18)V_d \times \frac{SO_2}{R}$$

Equation 13-9

H^+ is H^+ concentration in rain, V_d is deposition velocity of SO_2, SO_2 is SO_2 concentration in $\mu g/m^3$, and R is rain in m.

Damage functions for aluminum, zinc, copper, plastic, paint, and rubber have also been estimated and applied along with the "Lipfert function" for stone to evaluate potential damage to modern building materials expected in the 21st century. In the process, an extensive list of damage functions for a wide range of building materials from various sources was reviewed and published and used to predict potential damage to various materials under local air pollution and climate conditions, as shown in Figure 13-34 (Brimblecombe and Grossi, 2010).



Source: Permission pending, Brimblecombe and Grossi (2010).

Figure 13-34 Predictions of materials damage to various materials based on damage functions. Rate of damage (rate of mass loss per area in the case of aluminum, limestone, zinc, copper; rate of deterioration for plastic paint and rubber) is shown on the y axis. Years are shown on the x axis.

Damage functions were also used to estimate long-term deterioration of limestone, iron, and copper, and the blackening of stone surfaces in London between 1100−2100 using meteorological and pollution input (Brimblecombe and Grossi, 2009). Deterioration of limestone and possibly copper intensified in the 18th century, and soiling was especially rapid in the 19th century. Based on these observations it was concluded that damage to durable building material is no longer controlled by pollution as in earlier centuries, with natural weathering becoming a more important influence in modern times. However, even as damage to stone and metals from PM have decreased in modern times, potentially higher degradation rates for polymeric materials, plastic, paint, and rubber are predicted due to increased oxidant concentrations and solar radiation (Brimblecombe and Grossi, 2009).

13.4.5 Summary and Causality Determination

The conclusion in the 2009 PM ISA (U.S. EPA, 2009) that PM deposition can result in increased cleaning and maintenance costs and reduced usefulness of soiled material is supported by additional studies detailing new evidence , and there has been steady progress in understanding soiling and corrosion processes and developing approaches to quantify pollutant exposure corresponding to perceived soiling and damage, with respect to pollutant concentration, particle size, and chemical composition. The combination of this evidence further reinforces and supports the conclusion of the 2009 PM ISA of a causal relationship between PM and effects on materials. This section describes the evaluation of evidence for materials effects, with respect to the causality determination, using the framework described in Table II of the Preamble to the ISAs (U.S. EPA, 2015).

Materials damage from particulate matter and other pollutants generally involves one or both of two processes, soiling and corrosion (Section 13.4.2). Soiling is a visible darkening or decrease in reflectance of a material, and corrosion is damage to a material over time caused by chemical reactions with the material surface. Quantitative assessments of materials damage have been carried out by developing dose-response relationships (Section 13.4.3) and applying damage functions (Section 13.4.4), but much of the scientific literature on soiling, corrosion, dose-response relationships and damage functions have focused on stone used for historic monuments and buildings, and there has been a substantial gap in our understanding of processes and quantitative relationships involving other materials. It is still the case that the majority of the literature available on materials damage concerns cultural heritage and stone materials, including differences in elemental composition between crusts on building surfaces and unaffected stone surfaces, as well as documentation of an important role of microbial processes in stone decay.

Although most research on materials damage has concerned stone materials, there has been steady progress in understanding soiling and corrosion processes for glass and metals. These advances include modeling of glass soiling, identifying which pollutants are most influential in metal corrosion in a multipollutant environment, and how that varies between metals. Since the 2009 ISA characterization of

quantitative dose-response relationships and damage functions for materials besides stone has also progressed, with a new dose-response curves published for glass, and a new summary of available materials damage functions. In addition to structural damage, aesthetic qualities, and cleaning costs that are longstanding concerns for PM and air pollution effects, a growing body of research on PM and air pollution impacts concerns energy costs. Applications from climate control and energy consumption of large buildings to efficient operation of photovoltaic systems are influenced by atmospheric soiling. **Overall, the evidence is sufficient to conclude that a causal relationship exists between PM and effects on materials.**

APPENDIX 1 EVALUATION OF STUDIES ON HEALTH EFFECTS OF PARTICULATE MATTER

This appendix describes the approach used in the Integrated Science Assessment (ISA) for Particulate Matter (PM) to evaluate study quality in the available health effects literature. As described in the Preamble to the ISA (U.S. EPA, 2015), causality determinations were informed by the integration of evidence across scientific disciplines (e.g., exposure, animal toxicology, epidemiology) and related outcomes and by judgments of the strength of inference in individual studies. Table A-1 describes aspects considered in evaluating study quality of controlled human exposure, animal toxicological, and epidemiologic studies. The aspects found in Table A-1 are consistent with current best practices for reporting or evaluating health science data.[86] Additionally, the aspects are compatible with published U.S. EPA guidelines related to cancer, neurotoxicity, reproductive toxicity, and developmental toxicity (U.S. EPA, 2005, 1998, 1996, 1991).

These aspects were not used as a checklist, and judgments were made without considering the results of a study. The presence or absence of particular features in a study did not necessarily lead to the conclusion that a study was less informative or to exclude it from consideration in the ISA. Further, these aspects were not used as criteria for determining causality in the five-level hierarchy. As described in the Preamble, causality determinations were based on judgments of the overall strengths and limitations of the collective body of available studies and the coherence of evidence across scientific disciplines and related outcomes. Table A-1 is not intended to be a complete list of aspects that define a study's ability to inform the relationship between PM and health effects, but it describes the major aspects considered in this ISA to evaluate studies. Where possible, study elements, such as exposure assessment and confounding (i.e., bias due to a relationship with the outcome and correlation with exposures to PM), are considered specifically for PM. Thus, judgments on the ability of a study to inform the relationship between an air pollutant and health can vary depending on the specific pollutant being assessed.

[86]For example, NTP OHAT approach (Rooney et al., 2014), IRIS Preamble (U.S. EPA, 2013), ToxRTool (Klimisch et al., 1997), STROBE guidelines (von Elm et al., 2007), and ARRIVE guidelines (Kilkenny et al., 2010).

Table A-1 Scientific considerations for evaluating the strength of inference from studies on the health effects of particulate matter.

Study Design
Controlled Human Exposure
Studies should clearly describe the primary and any secondary objectives of the study, or specific hypotheses being tested. Study subjects should be randomly exposed without knowledge of the exposure condition. Preference is given to balanced crossover (repeated measures) or parallel design studies which include control exposures (e.g., to clean filtered air). In crossover studies, a sufficient and specified time between exposure days should be provided to avoid carry over effects from prior exposure days. In parallel design studies, all arms should be matched for individual characteristics such as age, sex, race, anthropometric properties, and health status. In studies evaluating effects of disease, appropriately matched healthy controls are desired for interpretative purposes.
Animal Toxicology
Studies should clearly describe the primary and any secondary objectives of the study, or specific hypotheses being tested. Studies should include appropriately matched control exposures (e.g., to clean filtered air, time matched). Studies should use methods to limit differences in baseline characteristics of control and exposure groups. Studies should randomize assignment to exposure groups and where possible conceal allocation to research personnel. Groups should be subjected to identical experimental procedures and conditions; animal care including housing, husbandry, etc. should be identical between groups. Blinding of research personnel to study group may not be possible due to animal welfare and experimental considerations; however, differences in the monitoring or handling of animals in all groups by research personnel should be minimized.
Epidemiology
Inference is stronger for studies that clearly describe the primary and any secondary aims of the study, or specific hypotheses being tested. For short-term exposure, time-series, case crossover, and panel studies are emphasized over cross-sectional studies because they examine temporal correlations and are less prone to confounding by factors that differ between individuals (e.g., SES, age). Panel studies with scripted exposures, in particular, can contribute to inference because they have consistent, well-defined exposure durations across subjects, measure personal ambient pollutant exposures, and measure outcomes at consistent, well-defined lags after exposures. Studies with large sample sizes and conducted over multiple years are considered to produce more reliable results. Additionally, multi-city studies are preferred over single-city studies because they examine associations large diverse geographic areas using a consistent statistical methodology, avoiding the publication bias often associated with single-city studies[a]. If other quality parameters are equal, multicity studies carry more weight than single-city studies because they tend to have larger sample sizes and lower potential for publication bias. For long-term exposure, inference is considered to be stronger for prospective cohort studies and case-control studies nested within a cohort (e.g., for rare diseases) than cross-sectional, other case-control, or ecologic studies. Cohort studies can better inform the temporality of exposure and effect. Other designs can have uncertainty related to the appropriateness of the control group or validity of inference about individuals from group-level data. Study design limitations can bias health effect associations in either direction.

Table A-1 (Continued): Scientific considerations for evaluating the strength of inference from studies on the health effects of particulate matter.

Study Population/Test Model
Controlled Human Exposure
In general, the subjects recruited into study groups should be similarly matched for age, sex, race, anthropometric properties, and health status. In studies evaluating effects of specific subject characteristics (e.g., disease, genetic polymorphism, etc.), appropriately matched healthy controls are preferred. Relevant characteristics and health status should be reported for each experimental group. Criteria for including and excluding subjects should be clearly indicated. For the examination of populations with an underlying health condition (e.g., asthma), independent, clinical assessment of the health condition is ideal, but self-report of physician diagnosis generally is considered to be reliable for respiratory and cardiovascular disease outcomes[b]. The loss or withdrawal of recruited subjects during the course of a study should be reported. Specific rationale for excluding subject(s) from any portion of a protocol should be explained.
Animal Toxicology
Ideally, studies should report species, strain, substrain, genetic background, age, sex, and weight. Unless data indicate otherwise, all animal species and strains are considered appropriate for evaluating effects of PM exposure. It is preferred that the authors test for effects in both sexes and multiple lifestages, and report the result for each group separately. All animals used in a study should be accounted for, and rationale for exclusion of animals or data should be specified.
Epidemiology
There is greater confidence in results for study populations that are recruited from and representative of the target population. Studies with high participation and low drop-out over time that is not dependent on exposure or health status are considered to have low potential for selection bias. Clearly specified criteria for including and excluding subjects can aid assessment of selection bias. For populations with an underlying health condition, independent, clinical assessment of the health condition is valuable, but self-report of physician diagnosis generally is considered to be reliable for respiratory and cardiovascular diseases[b]. Comparisons of groups with and without an underlying health condition are more informative if groups are from the same source population. Selection bias can influence results in either direction or may not affect the validity of results but rather reduce the generalizability of findings to the target population.
Pollutant
Controlled Human Exposure
Studies should: (1) include a composite measure of PM (i.e., $PM_{2.5}$, $PM_{10-2.5}$, or ultrafine particles [UFP][c]) or (2) apply some approach (e.g., particle trap or filter) to assess the effects of PM in a complex air pollution mixture (i.e., diesel exhaust, gasoline exhaust, wood smoke).
Animal Toxicology
Studies should: (1) include a composite measure of PM (i.e., $PM_{2.5}$, $PM_{10-2.5}$, or ultrafine particles [UFP][c]) or (2) apply some approach (e.g., particle trap or filter) to assess the effects of PM in a complex air pollution mixture (i.e., diesel exhaust, gasoline exhaust, wood smoke).
Epidemiology
Health effects are evaluated primarily using a composite measure of PM (i.e., $PM_{2.5}$, $PM_{10-2.5}$, or ultrafine particles [UFP][c]) from studies using ambient measurements, model predictions, or a combination of measured and modeled data. Studies of PM components must also include a composite measure of PM. Studies of source-related indicators are also evaluated where the indicator is derived using ambient PM concentrations.

Table A-1 (Continued): Scientific considerations for evaluating the strength of inference from studies on the health effects of particulate matter.

Exposure Assessment or Assignment
Controlled Human Exposure
For this assessment, the focus is on studies that utilize PM concentrations <2 mg/m^3. Studies that use higher exposure concentrations may provide information relevant to biological plausibility, dosimetry, or inter-species variation. Studies should have well-characterized pollutant concentration, temperature, and relative humidity and/or have measures in place to adequately control the exposure conditions. Preference is given to balanced crossover or parallel design studies which include control exposures (e.g., to clean filtered air). Study subjects should be randomly exposed without knowledge of the exposure condition. Method of exposure (e.g., chamber, facemask, etc.) should be specified and activity level of subjects during exposures should be well characterized.
Animal Toxicology
For this assessment, the focus is on studies that utilize PM concentrations <2 mg/m^3. Studies that use higher exposure concentrations may provide information relevant to biological plausibility, dosimetry, or inter-species variation. Studies should characterize pollutant concentration, temperature, and relative humidity and/or have measures in place to adequately control the exposure conditions. The focus is on inhalation exposure. Non-inhalation exposure experiments (i.e., intratracheal instillation [IT]) are informative for size fractions (e.g., $PM_{10-2.5}$) that cannot penetrate the airway of a study animal and may provide information relevant to biological plausibility and dosimetry. In vitro studies may be included if they provide mechanistic insight or examine similar effects as in vivo studies, but are generally not included. All studies should include exposure control groups (e.g., clean filtered air).

Table A-1 (Continued): Scientific considerations for evaluating the strength of inference from studies on the health effects of particulate matter.

Epidemiology
Of primary relevance are relationships of health effects with the ambient component of PM exposure. However, information about ambient exposure rarely is available for individual subjects; most often, inference is based on ambient concentrations. Studies that compare exposure assessment methods are considered to be particularly informative. Inference is stronger when the duration or lag of the exposure metric corresponds with the time course for physiological changes in the outcome (e.g., up to a few days for symptoms) or latency of disease (e.g., several years for cancer).
Given that the spatial variability of PM composite measures varies among size fractions, with more homogeneity for $PM_{2.5}$ than either $PM_{10-2.5}$ or UFP, the need for capturing spatial contrasts is stronger for $PM_{10-2.5}$ or UFP compared with $PM_{2.5}$. Validated measurements, whether averaged across multiple monitors or assigned from the nearest or single available monitor, adequately capture temporal or spatial variation in exposure to $PM_{2.5}$ due to the high correlation between personal exposure and ambient concentration. However, for more spatially heterogeneous $PM_{10-2.5}$ and UFP, the spatial correlation between personal exposure and ambient concentrations is lower. Similarly, PM components show increased spatial variability relative to $PM_{2.5}$. In this case, validated methods that capture the extent of variability for the particular study design (temporal vs. spatial contrasts) and location carry greater weight. Inference based on central site measurements can be adequate if correlated with personal exposures, closely located to study subjects, highly correlated across monitors within a location, used in locations with well-distributed sources, or combined with time-activity information.
In studies of short-term exposure, temporal variability of the exposure metric is of primary interest. For all PM size fractions, studies that incorporate time-activity data with personal or microenvironmental monitoring or modeling data may carry greater weight because residential, in-vehicle, and workplace PM exposures may differ in their temporal variability. Results for total personal and indoor PM exposure are other lines of evidence that may inform judgments about causality of PM because inference is based on an individual's microenvironmental exposures and the potential for copollutant confounding may be reduced compared to ambient exposures. Results for total personal exposure can inform understanding of the effects of ambient exposure when well correlated with ambient concentrations.
For long-term exposures, methods that well represent within-community spatial variation in individual exposure may be given more weight for spatially-variable ambient $PM_{10-2.5}$ or ultrafine particles. For $PM_{2.5}$, within-community variation in exposure is less important given that $PM_{2.5}$ tends to be more homogeneous.
Exposure measurement error often attenuates health effect estimates or increases the imprecision of the association (i.e., width of 95% CIs), particularly associations based on temporal variation in short-term exposure. However, exposure measurement error can bias estimates away from the null in some epidemiologic studies of long-term exposures where the PM size fraction is more spatially heterogeneous (i.e., $PM_{10-2.5}$ or UFP), depending on the locations of the monitor and sources with respect to the study population.
To streamline the health effects discussion on studies that are most policy-relevant, for those health categories where the 2009 PM ISA concluded a "causal relationship" the focus is on studies with mean $PM_{2.5}$ concentrations <20 $\mu g/m^3$. However, studies that examine a previously identified uncertainty or limitation in the evidence are evaluated even if mean $PM_{2.5}$ concentrations are >20 $\mu g/m^3$.
Outcome Assessment/Evaluation
Controlled Human Exposure
Endpoints should be assessed in the same manner for control and exposure groups (e.g., time after exposure, methods, endpoint evaluator) using valid, reliable methods. Blinding of endpoint evaluators is ideal, especially for qualitative endpoints (e.g., histopathology). For each experiment and each experimental group, including controls, precise details of all procedures carried out should be provided including how, when, and where. Time of the endpoint evaluations is a key consideration that will vary depending on endpoint evaluated. Endpoints should be assessed at time points that are appropriate for the research questions.

Table A-1 (Continued): Scientific considerations for evaluating the strength of inference from studies on the health effects of particulate matter.

Animal Toxicology
Endpoints should be assessed in the same manner for control and exposure groups (e.g., time after exposure, methods, endpoint evaluator) using valid, reliable methods. Blinding of endpoint evaluators is ideal, especially for qualitative endpoints (e.g., histopathology). For each experiment and each experimental group, including controls, precise details of all procedures carried out should be provided including how, when, and where. Time of the endpoint evaluations is a key consideration that will vary depending on endpoint evaluated. Endpoints should be assessed at time points that are appropriate for the research questions.
Epidemiology
Inference is stronger when outcomes are assessed or reported without knowledge of exposure status. Knowledge of exposure status could produce artefactual associations. Confidence is greater when outcomes assessed by interview, self-report, clinical examination, or analysis of biological indicators are defined by consistent criteria and collected by validated, reliable methods. Independent, clinical assessment is valuable for outcomes such as lung function or incidence of disease, but report of physician diagnosis has shown good reliability[b]. When examining short-term exposures, evaluation of the evidence focuses on specific lags based on the evidence presented in individual studies. Specifically, the following hierarchy is used in the process of selecting results from individual studies to assess in the context of results across all studies for a specific health effect or outcome: • Distributed lag models; • Average of multiple days (e.g., 0−2); • If a priori lag days were used by the study authors these are the effect estimates presented; or • If a study focuses on only a series of individual lag days, expert judgment is applied to select the appropriate result to focus on considering the time course for physiologic changes for the health effect or outcome being evaluated. When health effects of long-term exposure are assessed by acute events such as symptoms or hospital admissions, inference is strengthened when results are adjusted for short-term exposure. Validated questionnaires for subjective outcomes such as symptoms are regarded to be reliable[c], particularly when collected frequently and not subject to long recall. For biological samples, the stability of the compound of interest and the sensitivity and precision of the analytical method is considered. If not based on knowledge of exposure status, errors in outcome assessment tend to bias results toward the null.
Potential Copollutant Confounding
Controlled Human Exposure
Exposure should be well characterized to evaluate independent effects of PM of various size fractions. Studies should apply some approach (e.g., particle trap or filter) to assess the effects of PM when examining exposures to complex air pollution mixtures (i.e., diesel exhaust, gasoline exhaust, wood smoke).
Animal Toxicology
Exposure should be well characterized to evaluate independent effects of PM of various size fractions. Studies should apply some approach (e.g., particle trap or filter) to assess the effects of PM when examining exposures to complex air pollution mixtures (i.e., diesel exhaust, gasoline exhaust, wood smoke).

Table A-1 (Continued): Scientific considerations for evaluating the strength of inference from studies on the health effects of particulate matter.

Epidemiology
Not accounting for potential copollutant confounding can produce artefactual associations; thus, studies that examine copollutant confounding carry greater weight. The predominant method is copollutant modeling (i.e., two-pollutant models), which is especially informative when correlations are not high. However, when correlations are high (r > 0.7), such as those often encountered for UFP and other traffic-related copollutants, copollutant modeling is less informative. Although the use of single-pollutant models to examine the association between PM and a health effect or outcome are informative, ideally studies should also include copollutant analyses. Copollutant confounding is evaluated on an individual study basis considering the extent of correlations observed between the copollutant and PM, and relationships observed with PM and health effects in copollutant models.
Other Potential Confounding Factors[d]
Controlled Human Exposure
Preference is given to studies utilizing experimental and control groups that are matched for individual level characteristics (e.g., race/ethnicity, sex, body weight, smoking history, age) and time varying factors (e.g., seasonal and diurnal patterns).
Animal Toxicology
Preference is given to studies utilizing experimental and control groups that are matched for individual level characteristics (e.g., strain, sex, body weight, litter size, food and water consumption) and time varying factors (e.g., seasonal and diurnal patterns).
Epidemiology
Factors are considered to be potential confounders if demonstrated in the scientific literature to be related to health effects and correlated with PM. Not accounting for confounders can produce artefactual associations; thus, studies that statistically adjust for multiple factors or control for them in the study design are emphasized. Less weight is placed on studies that adjust for factors that mediate the relationship between PM and health effects, which can bias results toward the null. Confounders vary according to study design, exposure duration, and health effect and may include, but are not limited to the following: Short-term exposure studies: Meteorology, day of week, season, medication use, allergen exposure, and long-term temporal trends. Long-term exposure studies: Socioeconomic status, race, age, medication use, smoking status, stress, noise, and occupational exposures.
Statistical Methodology
Controlled Human Exposure
Statistical methods should be clearly described and appropriate for the study design and research question (e.g., correction for multiple comparisons). Generally, statistical significance is used to evaluate the findings of controlled human exposure studies. However, consistent trends are also informative. Detection of statistical significance is influenced by a variety of factors including, but not limited to, the size of the study, exposure and outcome measurement error, and statistical model specifications. Sample size is not a criterion for exclusion; ideally, the sample size should provide adequate power to detect hypothesized effects (e.g., sample sizes less than 3 are considered less informative). Because statistical tests have limitations, consideration is given to both trends in data and reproducibility of results.

Table A-1 (Continued): Scientific considerations for evaluating the strength of inference from studies on the health effects of particulate matter.

Animal Toxicology
Statistical methods should be clearly described and appropriate for the study design and research question (e.g., correction for multiple comparisons). Generally, statistical significance is used to evaluate the findings of animal toxicology studies. However, consistent trends are also informative. Detection of statistical significance is influenced by a variety of factors including, but not limited to, the size of the study, exposure and outcome measurement error, and statistical model specifications. Sample size is not a criterion for exclusion; ideally, the sample size should provide adequate power to detect hypothesized effects (e.g., sample sizes less than 3 are considered less informative). Because statistical tests have limitations, consideration is given to both trends in data and reproducibility of results.
Epidemiology
Multivariable regression models that include potential confounding factors are emphasized. However, multipollutant models (more than two pollutants) are considered to produce too much uncertainty due to copollutant collinearity to be informative. Models with interaction terms aid in the evaluation of potential confounding as well as effect modification. Sensitivity analyses with alternate specifications for potential confounding inform the stability of findings and aid in judgments of the strength of inference from results. In the case of multiple comparisons, consistency in the pattern of association can increase confidence that associations were not found by chance alone. Statistical methods that are appropriate for the power of the study carry greater weight. For example, categorical analyses with small sample sizes can be prone to bias results toward or away from the null. Statistical tests such as *t*-tests and Chi-squared tests are not considered sensitive enough for adequate inferences regarding PM-health effect associations. For all methods, the effect estimate and precision of the estimate (i.e., width of 95% CI) are important considerations rather than statistical significance.

[a](U.S. EPA, 2008).

[b]Murgia et al. (2014); Weakley et al. (2013); Yang et al. (2011); Heckbert et al. (2004); Barr et al. (2002); Muhajarine et al. (1997); Toren et al. (1993); Burney et al. (1989).

[c]UFPs are defined as particles <100 nm in size, but studies often include size fractions larger than 100 nm in the assessment of the relationship between UFP exposure and health effects.

[d]Many factors evaluated as potential confounders can be effect measure modifiers (e.g., season, comorbid health condition) or mediators of health effects related to PM (comorbid health condition).

the relationship between an air pollutant and health can vary depending on the specific pollutant being assessed.
